Decades of research have documented the effectiveness of a broad strategy involving multifaceted interventions. A number of individual-level treatments have proved effective for smokers who want help to quit. These approaches include brief clinical interventions (e.g., a physician taking 10 minutes or less to deliver advice and assistance about quitting); counseling (e.g., individual, group, or telephone counseling); behavioral cessation therapies (e.g., training in problem solving); and treatments with more person-to-person contact and intensity. Cessation medications found to be effective for treating tobacco dependence include nicotine replacement products, either over-the-counter (e.g., nicotine patch, gum, lozenge) or prescription (e.g., nicotine inhaler, nasal spray), and prescription non-nicotine medications such as bupropion SR, varenicline tartrate, or new agents such as cytisine.²⁶ A 2008 Cochrane review found no overall

difference in the effectiveness of the various forms of nicotine replacement therapy. The combination of medication and counseling is more effective for smoking cessation than either medication or counseling alone, with multiple counseling sessions increasing the success rate.

Reductions in smoking from any mechanism improve health outcomes, particularly when linked to lifestyle changes, including exercise and dietary control. Trials of nicotine replacement therapy using transdermal nicotine or nicotine chewing gum increase abstinence rates after cessation. Such pharmacologic programs, as well as physician-guided counseling, are cost-effective and should be provided as standard prevention services. Smoking low tar or low nicotine cigarettes rather than regular cigarettes appears to have little effect on reducing the risk of coronary heart disease. Although the elevated cardiovascular risks associated with smoking decrease significantly after cessation, the risk for development of cancer of the lungs, pancreas, or stomach persists for more than a decade, as does that for chronic obstructive pulmonary disease. Smoking cessation has clear benefit, but smoking reduction alone appears to have only a marginal effect.

A number of evidence-based methods for population-based smoking cessation also exist. The World Health Organization (WHO) Framework Convention on Tobacco Control, which began in 2005, has been one of the most widely accepted treaties in the history of the United Nations, with more than 170 parties covering 87% of the world's population. In 2008, the WHO introduced a package of evidence-based tobacco control measures to help countries implement the WHO Framework Convention. Entitled MPOWER, the measures include increasing prices of tobacco products; anti-tobacco media campaigns featuring graphic personal stories on the adverse health impacts of smoking; implementing smoke-free laws for workplaces and public places; barrier-free access to help quitting; and enforcing restrictions on tobacco advertising, promotion, and sponsorship.²⁴ Studies carried out after the implementation of pictorial package warnings in a number of countries consistently have shown that they significantly increase people's awareness of the harms of tobacco use. Increasing tobacco taxes have also been a highly effective way to reduce tobacco use.

Accomplishing the goal of Healthy People 2020 to reduce the U.S. national prevalence of cigarette smoking among adults to a target of 12% will require more extensive implementation of evidence-based tobacco control interventions. Only two states have funded tobacco control programs at Centers for Disease Control and Prevention (CDC)-recommended levels, whereas 27 states are funded at less than a quarter of these levels. State funding in tobacco control programs has in fact decreased during the last five years. Good monitoring also is important to track the extent and character of the tobacco epidemic and indicates how best to tailor policies.

Several advances in tobacco control have occurred recently in the United States.²⁷ Four new laws have reinvigorated the national effort, including implementation of the 2009 Family Smoking Prevention and Tobacco Control Act, which granted the U.S. Food and Drug Administration (FDA) the authority to regulate the manufacture, distribution, and marketing of tobacco products; the Children's Health Insurance Reauthorization Act; the Prevent All Cigarette Trafficking Act; and the Patient Protection and Affordable Care Act. These laws have granted federal agencies more authority and funding to regulate tobacco products, decrease youth access to tobacco, and increase access to treatment programs. In 2010, the U.S. Department of Health and Human Services presented its first national strategic plan for tobacco control, with 21 action steps involving coverage of cessation treatment, reduction of youth access to tobacco, investments in state and local tobacco control initiatives, and communication efforts to engage the public. A federal mass media campaign began in early 2012, using graphic personal stories on the adverse health impact of smoking.

In the context of these renewed efforts, however, the low success rates in smoking cessation continue to challenge clinicians. Preventing smoking in the first place should receive greater emphasis. Community education and physician-based primary prevention remain the most important components of any smoking reduction strategy.

Hypertension

Elevated blood pressure is a major risk factor for coronary heart disease, heart failure, cerebrovascular disease, peripheral arterial disease, renal failure, atrial fibrillation, and total mortality, as well as loss of cognitive function and increased incidence of dementia (see also Chapters 1, 43, and 44). The degree of blood pressure lowering relates linearly to risk reduction. Observational data indicate that death from both coronary heart disease and stroke increases progressively from blood pressure levels as low as 115 mm Hg systolic and 75 mm Hg diastolic. For patients 40 to 70 years of age, each increment of 20 mm Hg in systolic blood pressure or 10 mm Hg in diastolic blood pressure doubles the risk of cardiovascular disease across a blood pressure range of 115/75 to 185/115 mm Hg. *Prehypertension*, defined as systolic blood pressure between 120 to 139 mm Hg or diastolic blood pressure between 80 to 89 mm Hg, is associated with nearly twice the risk of MI and stroke in women compared with normal blood pressure. Hypertension often confers silent cardiovascular risk, and its prevalence is steadily increasing in the United States and worldwide.

Approximately 78 million—or 1 in 3—adults in the United States have high blood pressure, defined as systolic blood pressure of 140 mm Hg or greater or diastolic blood pressure of 90 mm Hg or greater or taking antihypertensive medicine.^{28,29} Men have a higher percentage of hypertension than women until the age of 45 years; between 45 and 64 years of age, men and women have similar percentages of hypertension; and after 64 years of age, a higher percentage of women have diagnosed hypertension than men (Fig. 42-3). The prevalence of hypertension increases markedly with age in all races and ethnicities. The age-adjusted prevalence of hypertension (both diagnosed and undiagnosed) in the period 2003 to 2006 was 75% for older women and 65% for older men. The prevalence of hypertension in the United States varies geographically, with the percentage of adults who had been told they were hypertensive ranging from 22.9% in Utah to 40.1% in Alabama.

Disparities in hypertension by racial and ethnic groups persist (Fig. 42-4). Blacks develop high blood pressure more often, and at an earlier age, than do whites and Mexican Americans and have higher average blood pressure levels. Among blacks, more women than men have hypertension. Data from the National Health and Nutrition Survey (NHANES) indicate that from 1988 to 1994 through 1999 to 2002, the prevalence of high blood pressure in adults increased from 35.9% to 41.4% among blacks, and it was particularly high among black women at 44.0%. By their 60s, more than 80% of non-Hispanic black women are classified as being hypertensive.³⁰ The prevalence of hypertension in blacks in the United States is among the highest in the world, and is increasing. According to data from NHANES 2001 to 2006, among those who were hypertensive, non-Hispanic blacks and Mexican Americans had 40% higher odds of having uncontrolled blood pressure than in non-Hispanic whites.³¹

(From Go AS, Mozaffarian D, Roger VL, et al: *Heart disease and stroke statistics—2013 update: A report from the American Heart Association*. *Circulation* 127:e6, 2013.)

FIGURE 42-4 Age-adjusted prevalence trends for high blood pressure in adults 20 years of age and older, by race/ethnicity and sex, based on data from NHANES 1988-1994, 1999-2004, and 2005-2010. NH = non-Hispanic. (From Go AS, Mozaffarian D, Roger VL, et al: Heart disease and stroke statistics—2013 update: A report from the American Heart Association. *Circulation* 127:e6, 2013.)

TABLE 42-1 Hypertension Awareness, Treatment, and Control: NHANES 1999-2004 and 2005-2010 by Race/Ethnicity and Sex

STUDY COHORT	AWARENESS (%)		TREATMENT (%)		CONTROL (%)	
	1999-2004	2005-2010	1999-2004	2005-2010	1999-2004	2005-2010
NH white males	71.2	77.5	61.2	69.4	41.0	50.1
NH white females	74.4	84.0	65.3	78.2	37.2	53.9
NH black males	69.1	77.5	58.1	66.9	32.3	39.7
NH black females	83.5	88.5	73.9	81.5	40.4	52.8
Mexican American males	57.0	64.8	41.8	54.0	23.3	35.1
Mexican American females	67.9	75.5	56.3	68.1	29.6	41.6

NH = non-Hispanic; NHANES = National Health and Nutrition Examination Survey. Data from NHANES (1999-2004, 2005-2010) and National Heart, Lung and Blood Institute.

As a result, compared with whites, blacks have a 1.3 times greater rate of nonfatal stroke, a 1.8 times greater rate of fatal stroke, a 1.5 times greater rate of death attributable to heart disease, and a 4.2 times greater rate of end-stage kidney disease. Within the black community, rates of hypertension vary substantially, with persons with the highest rates more likely to be middle-aged or older, less educated, overweight or obese, and physically inactive and more likely to have diabetes mellitus, but those with uncontrolled high blood pressure who do not take antihypertensive medication tending to be male and younger and to have infrequent contact with a physician.

Data from NHANES 2007 to 2010 indicate that 6% of U.S. adults have undiagnosed high blood pressure. Of those with hypertension who are 20 years of age or older, 81.5% were aware they were hypertensive; 74.9% were under current treatment, 52.5% had their hypertension under control, and 47.5% did not achieve control.²⁹ Rates of control differ substantially by ethnic and racial groups (Table 42-1). The

rates of control were lower in Mexican Americans (39.3%) than in non-Hispanic whites (54.9%) and non-Hispanic blacks (47.6%). Findings from the Reasons for Geographic and Racial Differences in Stroke (REGARDS) study support the success of efforts to raise awareness of prevalent hypertension and importance of receiving treatment among blacks but also show substantial persistent racial disparities with regard to the control of blood pressure, with the odds of control being 27% lower in blacks than in whites. No geographic disparities were found in hypertension awareness, treatment, and disease control.³²

These data indicate that most people know their hypertension status, but 47.5% do not have their hypertension controlled.²⁸ Awareness and treatment rates of hypertension have increased substantially. The control rates increased in both sexes, in non-Hispanic blacks, in Mexican Americans, and in those 60 years of age and older. Yet, although control of hypertension improved, control rates remain

low, particularly among older patients (Fig. 42-5). Data from the Framingham Heart Study show that among those 80 years of age or older, only 38% of men and 23% of women had blood pressures that met targets set forth in the National High Blood Pressure Education Program's clinical guidelines. Similarly, data from the Women's Health Initiative (WHI) observational study of nearly 100,000 postmenopausal women across the country indicate that despite similar treatment rates, older women maintain especially poor hypertensive control.

Among U.S. adults with hypertension, 8.9% meet the criteria for resistant hypertension (blood pressure $\geq 140/90$ mm Hg, despite reported use of antihypertensive medications from three different drug classes or drugs from four or more antihypertensive drug classes regardless of blood pressure). This segment represents 12.8% of the population taking antihypertensive medications.³³ On the other end of the spectrum, data from NHANES 1999 to 2006 indicate that 29.7% of U.S. adults 20 years or older have prehypertension, defined as untreated systolic blood pressure of 120 to 139 mm Hg or untreated diastolic blood pressure of 80 to 89 mm Hg and not having been told on two occasions by a physician or other health professional that they have hypertension. Prehypertension is associated with elevated relative and absolute risks for cardiovascular outcomes across the age spectrum, including an association with incident stroke, particularly in nonelderly persons and for those with blood pressure values in the higher prehypertension range.³⁴

In the United States, the prevalence of hypertension is increasing across all race/ethnicity and age groups. By 2030, the prevalence of hypertension is projected to increase 7.2% from 2013 estimates. Costs directly attributable to high blood pressure for the United States total almost \$131 billion annually in direct medical expenses and \$25 billion in lost productivity,³⁵ and projections show that by 2030, the total cost of high blood pressure will increase to an estimated \$343 billion.²⁹ Worldwide almost 1 billion adults have hypertension, 333 million in economically developed countries and 639 million in developing countries. By 2025, the total number of adults with hypertension is anticipated to top 1.5 billion. Hypertension causes 7.6 million premature deaths worldwide annually, with 80% of this burden occurring in low-income and middle-income countries.³⁶ Approximately three quarters of persons with hypertension (639 million) live in developing countries with limited health resources,

and where people have a very low awareness of hypertension and poor blood pressure control.^{37,38} The proportion of people with hypertension who have their hypertension under control in some countries, such as rural Ecuador, is as low as 0.3%. This high prevalence of hypertension and poor hypertension control contribute importantly to the rising epidemic of cardiovascular disease in developing countries. Several hypertension risk factors seem to be more common in developing countries than in developed regions, including urbanization, aging of the population, changes to dietary habits, and social stress. High illiteracy rates, limited access to health facilities, poor dietary habits, poverty, and high costs of drugs all contribute to poor blood pressure control.³⁷

Numerous risk factors and markers for development of hypertension have been identified, including increasing age, ethnicity, family history of hypertension, genetic factors, lower education and socioeconomic status, greater weight, lower physical activity, tobacco use, psychosocial stressors, sleep apnea, and dietary factors (including increased dietary fats, higher sodium intake, lower potassium intake, and excessive alcohol intake). Data suggest that controlling dietary and lifestyle risk factors can prevent a large proportion of incident hypertension in women.³⁹⁻⁴¹ Young women who adopt healthy practices such as maintaining normal weight, eating a healthful diet, exercising daily, drinking a moderate amount of alcohol, and limiting use of over-the-counter analgesics can greatly reduce the risk of hypertension.

Patients with concomitant chronic kidney disease (estimated glomerular filtration rate below 60 mL/min²) constitute a high-risk group for focused blood pressure treatment, both for the prevention of cardiovascular disease and to slow progression to end-stage renal disease. Patients with obesity, the metabolic syndrome, and diabetes also represent high-risk groups for treatment. High blood pressure occurs in more than two thirds of patients with type 2 diabetes, and its development coincides with the development of hyperglycemia.⁴² In patients with diabetes, hypertension confers an enhanced risk of cardiovascular disease. People with controlled diabetes have a similar cardiovascular risk to patients without diabetes but with hypertension. The 10-year risk of a cardiovascular event among women 30 to 74 years of age with uncontrolled hypertension is 6%; however, 56% of these events could be prevented if blood pressure were controlled to normal levels.

Approximately 69% of persons who have a first heart attack, 77% of those who have a first stroke, and 74% of those who have congestive heart failure have blood pressure 140/90 mm Hg or higher. Data indicate that recent (within the last 10 years) and remote antecedent blood pressure levels may contribute importantly to risk over and above the current blood pressure level. Data from the Harvard Alumni Health Study found that higher blood pressure in early adulthood was associated several decades later with higher risk for all-cause, cardiovascular and coronary heart disease mortality, but not stroke mortality.⁴³ Hypertension is associated with shorter overall life expectancy, shorter life expectancy free of cardiovascular disease, and more years lived with cardiovascular disease. Total life expectancy was 5.1 years longer for normotensive men and 4.9 years longer for normotensive women than for hypertensive people of the same sex at 50 years of age.

Part of the complexity of hypertension as a risk factor relates to changing definitions of risk and today's recognition that systolic blood pressure and pulse pressure can contribute as much to risk as

FIGURE 42-5 Extent of awareness, treatment and control of high blood pressure by age (data from NHANES 2005 to 2008). (From Go AS, Mozaffarian D, Roger VL, et al: *Heart disease and stroke statistics—2013 update: A report from the American Heart Association. Circulation* 127:e6, 2013.)

does diastolic blood pressure, contrary to decades of clinical teaching. Most epidemiologic studies now recognize the joint contributions of both systolic and diastolic blood pressure to the development of cardiovascular risk, an issue that has markedly changed strategies for risk detection. Isolated systolic hypertension, in particular, carries at least as much risk as diastolic blood pressure for the outcomes of total cardiovascular mortality and stroke. Evidence supports treatment of systolic hypertension, even in older adults. Isolated systolic hypertension thus appears to represent a distinct pathophysiological state in which elevated blood pressure reflects reduced arterial elasticity not necessarily associated with increased peripheral resistance or an elevation in mean arterial pressure. Systolic blood pressure remains the most useful clinical predictor of risk.

Pulse pressure, generally reflecting vascular wall stiffness, also predicts first and recurrent MI. Defined as the difference between systolic and diastolic blood pressures, pulse pressure appears to predict cardiovascular events independently, particularly heart failure. These data stress the importance of arterial compliance and stiffness in atherogenesis as well as in the development of left ventricular hypertrophy.

Ambulatory monitoring of blood pressure over 24 hours may provide a stronger predictor of cardiovascular morbidity and mortality than office-based measures. Studies of home blood pressure evaluation have yielded mixed results. In one cohort of elderly persons, self-measurement of blood pressure had better prognostic accuracy for vascular events than office-based evaluation; another study has determined that nocturnal hypertension diagnosed by continuous monitoring is associated with increased risk of congestive heart failure. By contrast, in a randomized trial comparing office with home blood pressure measurement, self-measurement allowed identification of those persons with “white coat” hypertension but did not greatly improve overall management or alter objective measures of compliance, such as left ventricular mass. A more recent trial indicates that home monitoring with consequent blood pressure control yields greater benefit when a web-based pharmacist is available for consultation.

Multiple national clinical guidelines support screening for adult high blood pressure and treatment for hypertension, including both lifestyle interventions and pharmacologic therapy.⁴⁴⁻⁴⁶ Several studies have evaluated the positive cost-effectiveness of the treatment of hypertension for primary prevention of coronary heart disease.⁴⁷

Interventions to Reduce Blood Pressure

Major overviews and randomized trials continue to demonstrate that blood pressure reductions as small as 3 to 5 mm Hg result in large and clinically significant reductions in risk for stroke, vascular mortality, congestive heart failure, and total coronary heart disease in middle-aged subjects, elderly persons, and specified high-risk patients such as those with diabetes and peripheral arterial disease⁴⁸ (see also Chapter 44).

Diet and lifestyle management remain the cornerstone of prevention of hypertension, and clinical trial evidence continues to accrue showing that adopting low-risk dietary measures along with weight reduction, particularly at the societal level, could substantially reduce the burden of blood pressure. A large body of clinical trial evidence supports the effectiveness of a number of pharmacologic agents. The 7th Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7)²⁸ suggested a new classification of blood pressure, with “prehypertension” defined as systolic blood pressure 120 to 139 mm Hg or diastolic blood pressure 80 to 89 mm Hg. The results of the Trial of Preventing Hypertension (TROPHY) support the feasibility of drug treatment of prehypertension to prevent progression to hypertension. Routine pharmacologic therapy for prehypertension in the presence of other major comorbid conditions such as diabetes, renal dysfunction, or known vascular disease should await further evidence of benefit. Outcome trials have not demonstrated the superiority of initiation of treatment for prehypertensive patients over initiating treatment at the time of hypertension diagnosis or the cost-effectiveness of this approach. By contrast, the guidelines recommend drug therapy for those with stage 1 hypertension (systolic blood pressure 140 to 159 mm Hg or diastolic blood

pressure 90 to 99 mm Hg) or stage 2 hypertension (systolic blood pressure higher than 160 mm Hg or diastolic blood pressure higher than 100 mm Hg).

The JNC 7 set a blood pressure goal of 140/90 mm Hg for most patients, and 130/80 mm Hg for those with cardiovascular disease, diabetes, or chronic kidney disease, based largely on expert opinion rather than evidence (see Chapter 44). The Guideline section following Chapter 44 provides a discussion of current guidelines for hypertension management, including the statement from members of the group appointed to the JNC 8 panel. Because the relation of blood pressure relates linearly to cardiovascular risk, a significant portion of the population-attributable risk occurs among those with blood pressure in the JNC 7 category of prehypertension. For all patients with blood pressure of 120/80 mm Hg or greater, JNC 7 recommends lifestyle modifications including smoking cessation, weight reduction if needed, increased physical activity, limited alcohol intake, limited sodium intake, adequate potassium and calcium intake, and adoption of the Dietary Approaches to Stop Hypertension (DASH) eating plan, a diet with a reduced content of saturated and total fat that also includes abundant fruits, vegetables, and low-fat dairy products. Initiation of drug therapy depends on blood pressure and the absolute level of risk. Most patients require more than one agent to achieve their blood pressure goals.

Meta-analyses have shown that the magnitude of blood pressure reduction determines reduction in cardiovascular risk more than drug choice, and that long-term control usually requires combination therapy, thereby making the choice of drug class less important. There is, however, sufficient evidence to recommend use of ACE inhibitors (or angiotensin receptor blockers [ARBs] in patients who are intolerant of ACE inhibitors), calcium channel blockers, or thiazide diuretics as first-line agents. Available evidence no longer supports the use of beta-adrenergic blocking agents (beta blockers) as first-line therapy for primary prevention, because of less benefit than with other drugs, particularly in elderly persons, and increasing evidence that the most frequently used beta blockers at usual doses carry an unacceptable risk of inducing type 2 diabetes.⁴⁹

Until recently, those older than 80 years of age had low treatment rates because of concern that most hypertension trials had upper age limits or did not present age-specific results, and that treatment might lead to kidney and other problems. The Hypertension in the Very Elderly Trial (HYVET), however, found that treatment of this growing patient population with a diuretic and an ACE inhibitor if needed was both safe and effective, reducing not only the risk of heart failure and death from stroke but also that of death from any cause.^{50,51}

Previous trials have demonstrated the effectiveness of treating systolic blood pressure to a goal of 140 mm Hg. Observational studies suggest that benefits of systolic blood pressure lowering may extend to levels below 120 mm Hg. Clinical guidelines recommend maintaining a systolic blood pressure of less than 140 mm Hg for healthy adults of all ages and less than 130 mm Hg for adults with kidney disease or diabetes.²⁸ Some controversy surrounds this guideline, because no clinical trials have determined specifically the most appropriate blood pressure target for persons with latent or overt coronary artery disease.⁵²⁻⁵⁴ The ACCORD (Action to Control Cardiovascular Risk in Diabetes) trial evaluated the potential benefits of targeting a systolic blood pressure level below 120 mm Hg versus a level below 140 mm Hg in 4733 patients with type 2 diabetes. After a mean of 4.7 years, the annual rate of the primary outcome, a composite of rates of nonfatal myocardial infarction, nonfatal stroke, and death from cardiovascular causes did not differ significantly between groups. The intensive therapy group experienced fewer strokes but more frequent serious adverse events attributable to blood pressure problems. The investigators concluded that the evidence did not justify a systolic blood pressure target below 120 mm Hg in patients with type 2 diabetes.⁵⁵ A meta-analysis identified the benefit of a goal blood pressure of 130/80 mm Hg for patients with hypertension and type 2 diabetes but less evidence for treatment below this value.⁵⁶ The ongoing National Institutes of Health (NIH)-funded SPRINT (Systolic Blood Pressure Intervention Trial) study will provide complementary information in nondiabetics about whether an intensive

treatment program aimed at reducing systolic blood pressure to a lower goal than currently recommended (less than 120 mm Hg) will reduce cardiovascular disease risk over a 4- to 6-year period from that achieved with standard blood pressure control (less than 140 mm Hg). Additional components of the study address this question among those older than 75 years of age (SPRINT-Senior), those with chronic kidney disease, and the effects of blood pressure reduction on memory and cognition (SPRINT-MIND).

Successful treatment of hypertension is difficult despite the availability of several classes of antihypertensive drug and the value of strategies to combat the effect of adverse lifestyle on blood pressure. From 5% to 30% of the overall hypertensive population have resistant hypertension. Approximately 10% of patients have true resistant hypertension without a modifiable cause. Promising therapeutic alternatives for patients with resistant hypertension include the development of novel drugs (including the new pharmacologic classes of endothelin A receptor antagonists, vasopeptidase inhibitors, and aldosterone synthase inhibitors as well as new molecules from current pharmacologic classes with additional properties in blood pressure or metabolism pathways), and new procedures and devices, including stimulation of arterial baroreceptors and catheter-based renal denervation.⁵⁷

Low-Density Lipoprotein (LDL) Cholesterol

Of plasma-based atherothrombotic risk factors, LDL cholesterol is the best-established risk factor causally linked to incident MI and cardiovascular death (see also Chapter 45). High LDL cholesterol levels consistently predict risk of future cardiovascular events in human populations. Animal studies in multiple species have shown a causal relationship between hypercholesterolemia and atherosclerosis. Knowledge of the LDL receptor pathway plus emerging understanding of the vascular biology of atherosclerosis provides biologic plausibility for the involvement of LDL in atherogenesis. Furthermore, human mutations in the LDL receptor that produce hypercholesterolemia on a monogenic basis lead to accelerated atherosclerosis as early as the first decade of life in patients with homozygous familial hypercholesterolemia, while those with heterozygous hypercholesterolemia develop disease approximately 10 to 15 years later. This observation has led to the useful office-based concept of a threshold “cumulative lifetime exposure” to LDL cholesterol that, when crossed, results in clinically evident atherosclerosis (Fig. 42-6). Other recently described mutations that affect LDL metabolism, such as those in the enzyme proprotein convertase subtilisin/kexin type 9 (PCSK9), result in life-long reductions in LDL cholesterol and reduced lifetime risks of events.⁵⁸ By contrast, lifetime exposure to moderately elevated levels of LDL cholesterol typically leads to clinical events in the

seventh and eighth decades (i.e., 60s and 70s). Finally, as described further on, interventions in large clinical trials to lower LDL cholesterol levels by various approaches (e.g., bile acid-binding resins, intestinal bypass surgery, HMG-CoA reductase inhibitors [statins]) have shown a reduction in cardiovascular events. Thus LDL cholesterol fulfills the criteria of modified Koch's postulates as one causative agent in atherosclerosis.

Several independent lines of evidence suggest that what is regarded as “normal” cholesterol levels in Western society exceeds levels that good health requires. In particular, certain rural agrarian societies with very low rates of atherothrombosis exhibit total and LDL cholesterol levels well below those accepted as normal in Western societies. Another line of evidence derives from phylogeny. Contemporary humans have much higher total and LDL cholesterol levels than those of many other species of higher organisms that thrive nonetheless.

Cholesterol levels measured early in life influence long-term cardiovascular risk and burden of risk factors for atherosclerosis, including hypercholesterolemia, correlate with autopsy-proven fatty streak and raised lesion formation in the arterial tree. Studies with long-term follow-up have suggested that cholesterol levels in youth correlate with long-term risk of MI. Thus substantial evidence suggests that the burden of risk for cardiovascular disease begins in young adulthood. Autopsy studies from the Korea and Vietnam conflicts and recent explorations of coronary anatomy by intravascular ultrasonography all indicate that atherosclerosis affects adolescents in Western society and that this early exposure to elevated levels of LDL cholesterol leads to premature disease in midlife.

Interventions to Lower LDL Cholesterol

All patients with elevated LDL cholesterol should undergo aggressive diet and exercise programs prior to the initiation of pharmacologic therapy. Lowering LDL cholesterol with statins in both primary and secondary prevention, however, is a cornerstone for cardiovascular therapeutics and an elegant demonstration of the power randomized control trials can have on the practice of medicine.

In a 2010 meta-analysis that included 21 separate statin trials and more than 129,000 participants, every 1.0 mmol/liter reduction in LDL cholesterol associated with a 22% reduction in vascular events and a 10% reduction in all-cause mortality.⁵⁹ Trials that compared statin therapy with placebo and trials that compared higher-intensity regimens with lower-intensity regimens showed similar effects. Of note, all subgroups evaluated showed risk reductions of similar magnitude, with no evidence of effect modification according to baseline LDL cholesterol level. With regard to side effects, no evidence was found for any increase in cancer or deaths from nonvascular causes.

As demonstrated in an even more comprehensive 2012 meta-analysis, the benefits associated with statin use are, if anything, at least as impressive in primary prevention as in secondary prevention.¹² Indeed, in the primary prevention trials (WOSCOPS, AFCAPS/TextCAPS, MEGA, and JUPITER), relative risk reductions were larger than those observed in the remaining trials of secondary prevention trials. Thus, for the endpoints of major coronary events, stroke, coronary revascularization, and major vascular events, the greatest relative risk reductions occur among patients at lowest absolute risk (Fig. 42-7)—suggesting that ever-earlier therapy over a lifetime of risk may be the best biologic way to handle elevated cholesterol levels. The recent JUPITER trial (described later in greater detail under High-Sensitivity C-Reactive Protein) demonstrated almost 50% reductions in MI and stroke with rosuvastatin in a primary prevention population with LDL cholesterol levels below 130 mg/dL at study entry.⁸ In this trial, even among those with baseline LDL cholesterol levels of less than 70 mg/dL showed clinical benefits. On the other hand, as described previously, those with higher absolute risk attain greater absolute risk reductions with statin use. Thus those with the highest baseline risk and who achieve the greatest LDL cholesterol reductions avoid the most vascular events and vascular deaths (Fig. 42-8).

Statins can have adverse effects. Some patients suffer myopathy while on statin therapy, an effect that may be genetically determined at least for simvastatin at higher doses. Statin therapy is associated with small increases in the risk of diabetes,⁶⁰ an effect that may be

FIGURE 42-6 The concept of a threshold for cumulative lifetime exposure to LDL cholesterol and the onset of clinically evident atherosclerotic disease. (From Horton JD, Cohen JC, Hobbs HH: PCSK9: A convertase that coordinates LDL catabolism. *J Lipid Res* 50(Suppl):S172, 2009.)

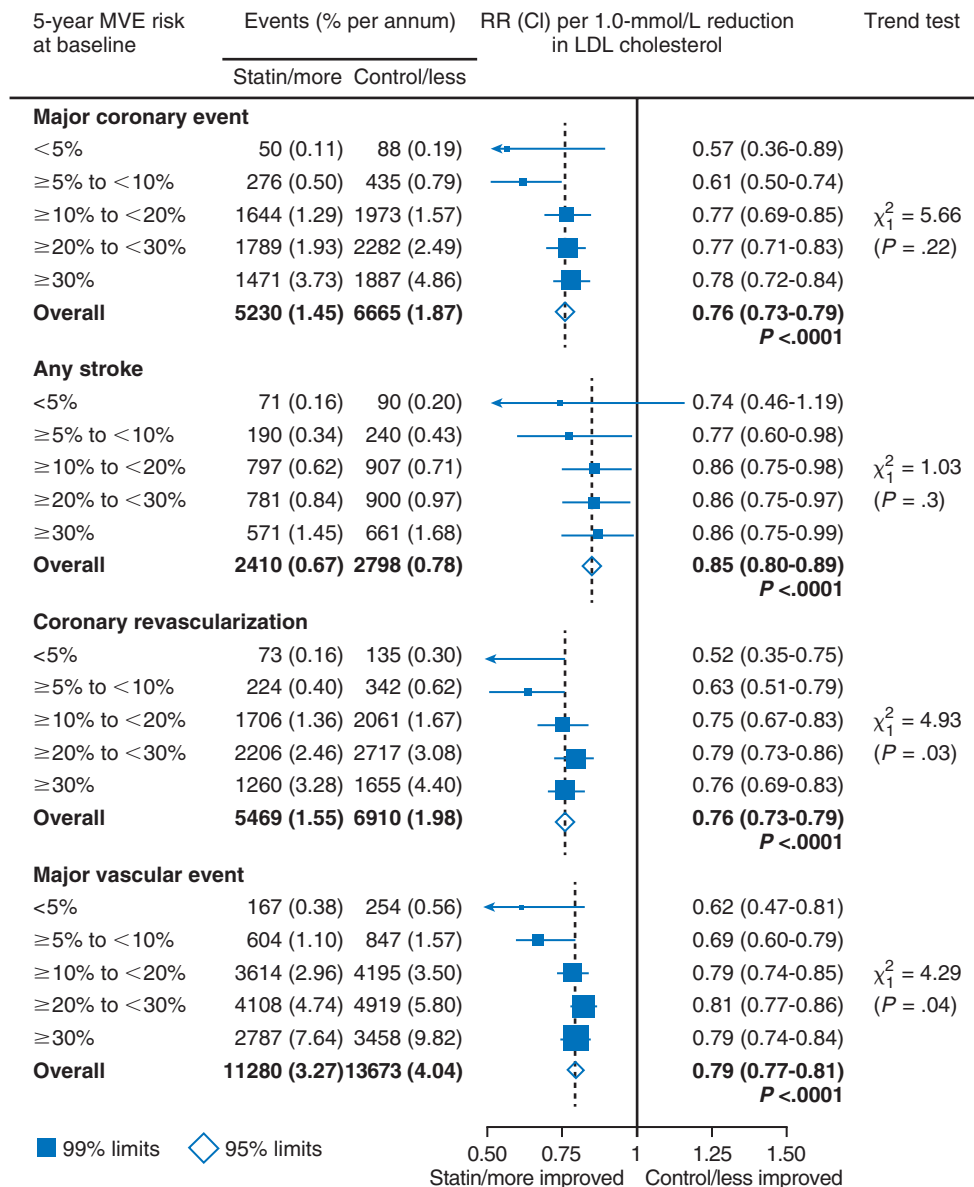

FIGURE 42-7 Effectiveness of statin therapy with each 1-SD reduction in LDL cholesterol at different levels of baseline risk. Data combined from 27 randomized trials. CI = confidence interval; MVE = major vascular event; RR = relative risk. (From the Cholesterol Treatment Trialists' (CTT) Collaborators, Mihaylova B, Emberson J, et al: The effects of lowering LDL cholesterol with statin therapy in people at low risk of vascular disease: Meta-analysis of individual data from 27 randomised trials. *Lancet* 380:581, 2012.)

greater with more intensive regimens.⁶¹ Development of diabetes occurs mostly in those who already have impaired fasting glucose, a group where the net benefits on preventing MI, stroke, and cardiovascular death outweigh these risks, even in primary prevention.¹¹ As discussed earlier with regard to trials of congestive heart failure and renal failure, high absolute risk does not automatically indicate that statin therapy will be effective. Yet for most patients, after initiation of diet, exercise, and smoking cessation, the best evidence supports addition of statin therapy among available pharmacologic interventions, an option that has become increasingly cost-effective as potent generic statin agents become available.

Not all agents that lower LDL cholesterol lower vascular event rates, so physicians should exercise caution when using nonstatin agents in both primary and secondary prevention. Ongoing clinical trials are evaluating agents that reduce cholesterol absorption, that inhibit PCSK9,⁶² and that inhibit LDL production and metabolism, although investigative studies of several novel pathways are under way. The evidence that life-long reductions in LDL cholesterol on a genetic basis lead to substantial reductions in vascular event rates and that

maximal doses of statin therapy can result in significant regression of coronary atherosclerosis guides these trials.⁶³ Side effects of these newer agents are currently unknown although post hoc analyses of high-potency statin trials suggest that lowering LDL cholesterol below 50 mg/dL should be safe for many patients.

High-Density Lipoprotein (HDL) Cholesterol

As is the case with LDL cholesterol, abundant prospective epidemiologic data demonstrate a strong inverse relationship between HDL cholesterol and vascular risk. In general, observational data suggest that each incremental increase in HDL cholesterol of 1 mg/dL is associated with a 2% to 3% decrease in risk of total cardiovascular disease. Patients with angiographically proven coronary artery disease more often have low levels of HDL than high levels of LDL, as defined by current criteria. The process of reverse cholesterol transport may contribute to the apparent protective role of HDL against coronary death. According to this concept, HDL could ferry cholesterol from the vessel wall, augmenting peripheral catabolism of cholesterol. HDL also can carry antioxidant enzymes that may

reduce the levels of oxidized phospholipids in atheromatous lesions, which might enhance atherogenesis. Furthermore, overexpressing the apolipoprotein A-I (apo A-I) gene in transgenic mice and infusing complexes of apo A-I and phospholipids into hyperlipidemic rabbits not only increases HDL cholesterol levels but also decreases atherosclerotic development. HDL also may have anti-inflammatory properties and promote cholesterol efflux from macrophages.⁶⁴ For all of these reasons, measurement of HDL figures in all global risk prediction algorithms, and the ratio of total to HDL cholesterol remains among the most potent lipid-based predictors of cardiovascular risk. Furthermore, in several studies, on-treatment levels of HDL cholesterol after statin therapy have correlated with residual risk,⁶⁵ but not in the JUPITER trial, where LDL cholesterol levels fell on statin therapy to a median level of 50 mg/dL.⁶⁶

Interventions to Raise HDL Cholesterol

Despite the considerable strength of epidemiologic evidence inversely linking plasma HDL cholesterol levels to vascular risk, such evidence is lacking for a reduction in vascular event rates consequent to increasing HDL in association with any intervention. To the contrary, large-scale endpoint trials completed to date have found no benefit in terms of occurrence of clinical events and in some cases have carried a suggestion of harm. For example, in the recent AIM-HIGH trial, random allocation of high-risk patients to niacin supplementation resulted in a significant increase in HDL cholesterol (as well as reductions in triglycerides and LDL cholesterol), yet no beneficial

effect on clinical event rate was observed.⁶⁷ Initial reports from the large HPS2-THRIVE trial also indicate no cardiovascular benefit from niacin. Similarly, in the ACCORD trial, fenofibrate reduced triglycerides and increased HDL cholesterol yet produced no significant reduction in hard vascular events.⁶⁸ Of concern, in the Investigation of Lipid Level Management to Understand Its Impact in Atherosclerotic Events (ILLUMINATE) trial, in which patients at high vascular risk who received the cholesteryl ester transfer protein (CETP) inhibitor torcetrapib showed an unanticipated increase in all-cause mortality.⁶⁹ Although some of this hazard probably resulted from off-target effects, a second major trial using the CETP inhibitor dalcetrapib also failed to reduce cardiovascular event rates despite a 30% to 40% increase in HDL cholesterol.⁷⁰ Recent mendelian randomization studies also raise the possibility that at least some genetic mechanisms that raise plasma HDL cholesterol levels do not lower MI risk—challenging the concept that raising HDL will necessarily reduce vascular event rates.⁷¹

Nonetheless, the consistency of the observational data, both cross-sectional and prospective, strongly supports HDL cholesterol level as a “negative” risk marker, as incorporated in guidelines worldwide, and supports the continued careful evaluation of agents that can directly increase HDL levels. The recognition that a biomarker can have clinical usefulness without being in the causal pathway for disease and fulfilling modified Koch’s postulates has importance for clinical practice and has implications for several other emerging risk factors such as those that measure vascular inflammation (see also Chapter 10).

Alternative Lipid and Lipoprotein Measures

LDL particles exhibit considerable heterogeneity. Small, dense LDL particles are associated with high levels of triglycerides, low levels of HDL cholesterol, increased inflammation, and considerably increased cardiovascular risk, a common scenario in diabetic patients. By contrast, larger and less dense LDL particles appear less likely to be associated with acute vascular events. In univariate analyses, several studies suggest that the measurement of LDL’s major apolipoprotein, apo B predicts cardiovascular risk better than LDL cholesterol in clinical practice. Most of these studies find, however, that non-HDL cholesterol (defined as total cholesterol minus HDL cholesterol) provides clinical risk information as least as strong as that for apo B—an observation that is not surprising, because non-HDL cholesterol correlates very closely with apo B levels. Furthermore, most studies report that the total cholesterol-to-HDL cholesterol ratio remains a very strong predictor of risk, superior even to the ratio of apo B to apo A-I, the dominant apolipoprotein carried by HDL cholesterol. Thus, despite evidence favoring apo A-I and apo B100 in univariate analyses as replacements for HDL and LDL cholesterol, only marginal clinical data seem to indicate that use of these measures improves overall risk prediction compared with standard lipid testing. In a recent comprehensive meta-analysis of 37 prospective cohort studies of patients without known cardiovascular disease, the addition of information on apo B and apo A-I led to only slight improvements in risk prediction.⁷² Among patients treated with statin therapy, similar overviews have found that on-treatment levels of LDL cholesterol, non-HDL cholesterol and apo B each were associated with risk of recurrent vascular events, but non-HDL cholesterol showed the greatest strength of association.⁶⁵ Whether this relative advantage has clinical importance in current practice is uncertain; among patients treated with more potent statin agents, recent analyses suggest that on-treatment LDL cholesterol predicts residual risk as well as does non-HDL cholesterol, apo B, or lipid ratio.⁷³

Beyond standard chemical measures of total, LDL, and HDL cholesterol (which appropriately form the basis of current lipid screening and reduction guidelines), the amount of cholesterol carried by different classes of lipoprotein particles may influence specific functions and vary widely among individuals. Therefore measures of core lipid composition and lipoprotein particle size might provide better measures for risk prediction. Several lines of evidence have indicated that small LDL particles may be more atherogenic than large particles

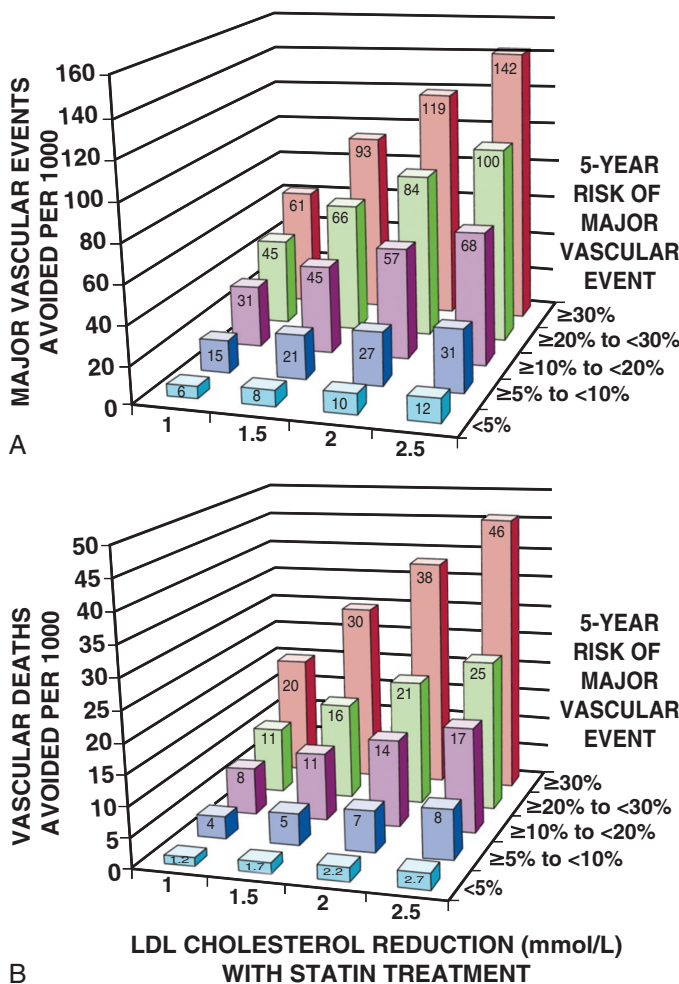

FIGURE 42-8 Predicted 5-year benefits in terms of major vascular events avoided (**A**) and vascular deaths prevented (**B**) with statin therapy at different levels of risk. (From the Cholesterol Treatment Trialists’ (CTT) Collaborators, Mihaylova B, Emberson J, et al: The effects of lowering LDL cholesterol with statin therapy in people at low risk of vascular disease: Meta-analysis of individual data from 27 randomised trials. *Lancet* 380:581, 2012.)

and contribute particularly to the dyslipidemia of diabetes. Currently, a number of technologies can evaluate LDL subclasses and particle size. Studies using density gradient ultracentrifugation and gradient gel electrophoresis generally have found that lipoprotein subclass identifies patients at higher risk for coronary disease and have shown a preferential benefit of lipid-lowering therapy for those with small, dense LDL particles as compared with large LDL particles. Studies also have found LDL particle concentration, as measured by nuclear magnetic resonance (NMR) imaging studies, to correlate well with coronary arterial lumen diameter after statin therapy and to predict future vascular events. In the Women's Health Study, LDL particle concentration measured by nuclear magnetic resonance predicted incident vascular events better than standard chemical measurement of LDL cholesterol.⁷⁴ In this study, however, lipoprotein profiles evaluated by NMR did not show superiority to standard measures such as the total-to-HDL cholesterol ratio or non-HDL cholesterol. HDL particle concentration (HDL-P), as measured by NMR, also may predict residual risk after statin therapy to a greater extent than HDL size or chemical HDL cholesterol. Thus, although data for advanced lipid testing continue to accrue, it remains unclear whether novel methods of lipid evaluation add importantly to standard lipid screening in routine practices or should remain specialized tools for research and lipid clinics. In this regard, the most recent recommendations from the National Lipid Association recommend caution when using any novel lipid measure among those at low risk, although LDL particle concentration (LDL-P) and apo B level were considered "reasonable" for use among patients at intermediate risk.⁷⁵

Triglycerides

Plasma triglycerides are primarily produced in the intestines (where dietary triglycerides rapidly enter the circulation within circulating chylomicrons) and within the liver (where triglycerides assembled from de novo synthesized fatty acids are secreted in very-low-density lipoprotein [VLDL]) (see also Chapter 45). Several factors regulate plasma triglyceride concentrations, most prominently HDL cholesterol itself. In part for these reasons, in contrast with compelling evidence favoring a causal role for LDL cholesterol in atherogenesis, the role of triglycerides remains uncertain. One aspect of this controversy is the inverse correlation of triglyceride levels with HDL cholesterol, such that adjustment for HDL cholesterol attenuates the relationship between triglycerides and cardiovascular disease. Meta-analyses suggest that the adjusted risk ratio for coronary disease among patients with triglyceride levels in the top third of reported values compared with those in the bottom third decreased from approximately 2.0 to 1.5 after accounting for HDL cholesterol.⁷⁶

Dietary production of triglycerides also complicates clinical application, because guidelines continue to recommend measurement of triglycerides in the fasting state, yet accumulating evidence indicates that much of the prognostic value of plasma triglyceride levels derives from postprandial levels. Several major cohort studies report that nonfasting triglycerides predict vascular events, independent of traditional risk factors.^{77,78} On this basis, some investigators suggest adoption of nonfasting triglyceride levels to predict vascular risk.

Interventions to Reduce Triglyceride Levels

Dietary discretion, exercise, and weight reduction as recommended for LDL cholesterol control also have relevance for triglyceride management. Agents approved by the FDA for the reduction of triglyceride levels include omega-3 fatty acid supplements and fibrates, but a recent meta-analysis of randomized trials evaluating the effects of omega-3 supplementation on all-cause mortality, MI, and stroke found no evidence that lowering triglycerides through this mechanism reduces vascular event rates.⁷⁹ Furthermore, in the large-scale Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial of high-risk patients with impaired fasting glucose or diabetes, the use of omega-3 fatty acid supplementation reduced triglycerides but had no effect on rates of major vascular events.⁸⁰ With regard to fibrates, both the FIELD⁸¹ and ACCORD⁶⁸ trials failed to show significant reductions in vascular events with triglyceride lowering using

fibric acid derivatives, although subgroup analyses raise the hypothesis that further trials focused on patients with elevated triglycerides and low levels of HDL cholesterol merit consideration.

For these reasons, current guidelines do not establish a target value for triglycerides, and pharmacologic triglyceride reduction is not broadly recommended other than for patients at high risk for pancreatitis. Yet, in view of the tight link of triglyceride levels with known risk factors for atherosclerosis (e.g., low HDL cholesterol level, uncontrolled diabetes, hypothyroidism), the finding of marked and persistently elevated triglyceride levels should enter into overall risk assessment for an individual and stimulate consideration of the reason for triglyceride level elevation, including careful exclusion of secondary causes such as excessive alcohol consumption, renal disease, Cushing syndrome, and hypothyroidism or the use of concomitant medications such as estrogen, corticosteroids, cyclosporine, and protease inhibitors. Genetic studies also support a causal role for triglycerides in atherogenesis, thus encouraging continued research into triglyceride-lowering approaches.⁸²

Metabolic Syndrome, Insulin Resistance, and Diabetes

Insulin resistance and diabetes rank among the major cardiovascular risk factors; the presence of diabetes confers an equivalent risk to aging 15 years, an impact comparable with if not greater than that of smoking (see also Chapter 61). Almost 35 million people in the United States have some degree of abnormal glucose tolerance, a condition along with obesity that markedly increases the risk for type 2 diabetes and premature atherothrombosis. Patients with diabetes have twofold to eightfold higher rates of future cardiovascular events as compared with age- and ethnically matched nondiabetic subjects, and 75% of all deaths in diabetic patients result from coronary heart disease. Compared with unaffected persons, diabetic patients have a greater atherosclerotic burden in the major arteries, as well as of microvascular disease. Not surprisingly, diabetic patients have substantially increased rates of atherosclerotic complications in the settings of primary prevention and after coronary interventional procedures. Insulin resistance alone confers an elevated risk of congestive heart failure and probably explains the association of obesity with this common vascular complication. Moreover, the risk of cardiovascular disease starts to increase long before the onset of clinical diabetes. In an analysis of data from the Nurses Health Study on women who eventually developed type 2 diabetes, the relative risk of MI was elevated threefold *before* the diagnosis of diabetes, for a cardiovascular event rate almost as high as the rate in patients with frank diabetes at study entry.⁸³ These effects loom even larger in ethnic minority populations and in patients with other concomitant risk factors.

Although hyperglycemia is associated with microvascular disease, insulin resistance itself promotes atherosclerosis even before it produces frank diabetes, and available data corroborate the role of insulin resistance as an independent risk factor for atherothrombosis. This finding has prompted recommendations for increased surveillance for the *metabolic syndrome*, a cluster of glucose intolerance and hyperinsulinemia accompanied by hypertriglyceridemia, low HDL levels, hypofibrinolysis, hypertension, microalbuminuria, a predominance of small dense LDL particles, and central obesity. Although several formal definitions of the metabolic syndrome have been proposed, the definition adopted by the National Cholesterol Education Program Adult Treatment Panel requires at least three of the following five criteria: (1) waist circumference larger than 102 cm in men and 88 cm in women; (2) serum triglyceride levels of at least 150 mg/dL; (3) HDL cholesterol less than 40 mg/dL in men and less than 50 mg/dL in women; (4) blood pressure of at least 130/85 mm Hg; and (5) serum glucose concentration of at least 110 mg/dL. Using these criteria, metabolic syndrome has a prevalence of almost 25% (affecting almost 50 million persons) in the United States alone.

Some investigators have raised concerns regarding the concept of metabolic syndrome. Indeed, the definition of "metabolic syndrome" varies among various national guidelines and statements. Some of

these criteria require measurement of insulin resistance whereas others, including the Adult Treatment Panel III criteria, use variables readily available from a standard clinical evaluation. The very disparity in the definitions underscores the arbitrary nature of including or excluding various risk factors in the definition of metabolic syndrome. Moreover, controversy continues regarding insulin resistance as a unifying pathophysiologic pathway that accounts for all of the features of the so-called metabolic syndrome, rendering it a true “syndrome.” In addition, the question of whether coalescence of risk factors incorporated in the concept of metabolic syndrome augment risk over and above the sum of risk attributable to the individual components remains controversial.

Nonetheless, several studies have documented that persons with the metabolic syndrome have elevated vascular event rates. In the Kuopio Ischaemic Heart Disease Risk Factor Study, patients with metabolic syndrome showed markedly increased rates of coronary, cardiovascular, and all-cause mortality.⁸⁴ Other analyses focus on abnormalities of fasting glucose and reach similar conclusions. As a prominent example, in the Emerging Risk Factors Collaboration, even small increases in fasting glucose associated with increased rates of vascular deaths, cancer deaths, and nonvascular, noncancer deaths⁸⁵ (Fig. 42-9). Although most definitions of the metabolic syndrome include a measurement of “central obesity,” none of the current criteria include a direct measurement of visceral fat deposition. Much evidence supports the visceral adipose depot as a driver of dysmetabolism, including many components of the metabolic syndrome. The most recent definition of metabolic syndrome from the National Heart, Lung and Blood Institute (NHLBI) includes a proinflammatory state. Thus inflammatory biomarkers such as hsCRP may help further stratify clinical risk and improve the prognostic value of metabolic syndrome. For example, data from the Women’s Health Study have indicated that an hsCRP level greater than 3 mg/liter adds important prognostic information about cardiovascular risk at all levels of the metabolic syndrome, whereas those with levels less than 1 mg/liter are at substantially lower risk⁸⁶ (Fig. 42-10). This observation is clinically relevant, because levels of hsCRP also predict incident type 2 diabetes. Because hsCRP levels correlate with systemic hypofibrinolysis and with basal insulin levels, hsCRP evaluation may well become a routine part of the definition of metabolic syndrome. As reviewed later on in descriptions of inflammatory markers, this conclusion has emerged in part from observations that atherosclerosis and type 2 diabetes share a common inflammatory basis.⁸⁷

Because traditional risk algorithms and metabolic syndrome definitions do not capture inflammation explicitly, integrating features of

the “metabolic syndrome” may explain part of the usefulness of hsCRP in adding to cardiovascular risk prediction to traditional instruments such as the Framingham algorithm. Obesity and intra-abdominal fat, which require imaging studies for rigorous definition, account for part, but not all, of hsCRP’s ability to refine cardiovascular risk prediction. Obesity itself does not necessarily raise cardiovascular risk. Persons with predominantly subcutaneous fat, in the gynoid or “pear” distribution, have less cardiovascular risk for a given body mass index than those with the centripetal android or “apple” pattern associated with visceral adiposity. Some obese persons do not develop insulin resistance or other cardiovascular risk factors related to the metabolic syndrome. This observation has given rise to the concept of the “fit fat.” For this reason, body mass index itself may not predict incremental cardiovascular risk as well as do biomarkers of systemic inflammation.

FIGURE 42-10 The hs-CRP level adds prognostic information on risk for patients with and without metabolic syndrome. CVD = cardiovascular disease. (From Ridker, PM, Buring JE, Cook NR, Rifai N: C-reactive protein, the metabolic syndrome, and risk of incident cardiovascular events: An 8-year follow-up of 14,719 initially healthy American women. *Circulation* 107:391, 2003.)

FIGURE 42-9 Hazard ratios for major causes of death according to baseline levels of fasting glucose. CI = confidence interval. (From the Emerging Risk Factors Collaboration, Seshasai SR, Kaptoge S, et al: Diabetes mellitus, fasting glucose, and risk of cause-specific death. *N Engl J Med* 364:829, 2011.)

TABLE 42-2 Controversy Regarding the Metabolic Syndrome Concept

Summary of Concerns about the Metabolic Syndrome
Criteria are ambiguous or incomplete; rationale for thresholds is ill-defined.
Value of including diabetes in definition is questionable.
Insulin resistance as a unifying cause is uncertain.
No clear basis for including or excluding other cardiovascular risk factors
Cardiovascular risk value is variable and dependent on specific risk factors present.
Cardiovascular risk associated with the syndrome seems to be no greater than that for the sum of its parts.
Treatment of syndrome is no different from treatment for each of its components.
Medical value of diagnosing the syndrome is unclear.

Modified from Kahn R: Metabolic syndrome: What is the clinical usefulness? *Lancet* 371:1892, 2008.

Many clinicians find the concept of metabolic syndrome useful because it fits the profile of many patients presenting in primary care in contemporary practice. Some argue that the concept of metabolic syndrome can encourage physicians to engage in tighter control of risk factors and lifestyle modification and to encourage patients to adhere to lifestyle modification or therapy designed to address the individual components of metabolic syndrome as mandated by prevailing guidelines. Skeptics, however, note the lack of evidence that the construct of metabolic syndrome can influence physicians or the public to adopt or maintain a healthy lifestyle or preventive therapies (Table 42-2). Thus controversy continues regarding the clinical usefulness of metabolic syndrome in preventive practice, at least as currently defined.

In the end, the controversy regarding the concept of the metabolic syndrome, its validity, and its clinical usefulness may present a false dichotomy. Given the growing epidemic of obesity and the foreseen burden of cardiovascular risk that it entails, professionals should reach beyond pedantic arguments regarding the nosology of the metabolic syndrome and combine forces to address the risk factors that make up this constellation. At issue in particular is the lack of evidence that in terms of factor-specific risk, the aggregate of syndrome characteristics does not outweigh the sum of its individual parts in younger populations, in which concern regarding obesity and cardiovascular risk has become urgent. All persons with components of the metabolic syndrome should adopt and adhere to a healthy lifestyle and should begin appropriate treatment for individual risk factors.

In addition to systemic metabolic abnormalities, hyperglycemia causes accumulation of advanced glycation end products associated with vascular damage. Diabetic patients have impaired endothelial vasodilator function and appear to have increased leukocyte adhesion to vascular endothelium, a critical early step in atherogenesis. Diabetic nephropathy, detected by microalbuminuria, accelerates these adverse processes. Among persons with non-insulin-dependent diabetes, microalbuminuria predicts cardiovascular and all-cause mortality. Diabetic and prediabetic patients also commonly have abnormalities of endogenous fibrinolysis. These effects, in concert with the impaired endothelium-dependent (nitric oxide-mediated) vasodilation common in diabetic patients, contribute to endothelial cell dysfunction and accelerated atherogenesis.

A particular area of concern is the role of childhood adiposity as a future determinant of adult diabetes and vascular risk. Two recent observational cohort studies have found that overweight or obese children who become obese adults suffer concomitant increases in risks for development of type 2 diabetes, hypertension, dyslipidemia, and early-onset atherosclerosis, whereas obese children who avoid adult obesity are spared many of these complications.^{88,89}

Interventions to Reduce Cardiovascular Risk among Diabetic Patients

Therapeutic interventions for patients with diabetes are reviewed elsewhere in this book. As demonstrated in the Diabetes Control and Complication Trial and in other trial settings, lifestyle management focusing on diet and exercise can reduce vascular risk in diabetic patients. Unfortunately, poor control of concomitant risk factors in diabetics constitutes a major challenge; in NHANES, only 31% of participants achieved the target goal of HbA_{1c} less than 7.0%, only 36% achieved the target blood pressure goals of less than 130/80 mm Hg, and more than half had total cholesterol levels in excess of 200 mg/dL; moreover, only 7% of all adults with diabetes in NHANES achieved all three of these crucial target goals. Social effects also are relevant for diabetes prevention. In a unique social experiment conducted by the Department of Housing and Urban Development, the opportunity to move from neighborhoods with high poverty levels to those with low poverty levels was associated with reductions in both obesity and incident diabetes.⁹⁰

In contrast with the case for lipid lowering, surgical approaches to diabetes and diabetes prevention have on several occasions proved superior to medical approaches. In a large Swedish trial in nondiabetic obese patients, bariatric banding, vertical gastropasty, or gastric bypass surgery markedly reduced incident diabetes when compared with medical intervention alone.⁹¹ Similarly, among those with diabetes, two recent trials suggest that bariatric surgery is superior to medical therapy for long-term glycemic control, although this effect may be unrelated to weight loss.^{92,93} These successes contrast with the failure of n-3 fatty acids to reduce vascular risk in patients with impaired fasting glucose or frank diabetes⁸⁰ and neutral effects for more aggressive and early control of glucose in this setting.^{94,95} To date, interventions to improve fitness and lose weight also have been disappointing; in the NIH-sponsored Look AHEAD trial, overweight or obese adults with diabetes were allocated to an intensive lifestyle intervention that promoted weight loss through decreased caloric intake and increased physical activity, or to a diabetes support and education program. The intensive lifestyle intervention focusing on weight loss did not reduce the rate of cardiovascular events in this group during a median follow-up period of almost 10 years, despite beneficial effects on levels of several biomarkers.⁹⁶

Aspirin for Primary Prevention

Low-dose aspirin therapy has clearly and consistently shown substantial net benefit for persons at high risk for subsequent events secondary to existing cardiovascular disease. Meta-analyses have demonstrated clear reductions in mortality and nonfatal cardiovascular events among those with a previous MI, stroke, bypass surgery, angioplasty, peripheral vascular surgery, or angina.⁹⁷ Doses above 75 mg/day showed clear benefit, with no trend toward increasing benefit for higher doses. Below 75 mg, a nonsignificant attenuated risk reduction of only 15% was noted. Other antiplatelet agents did not offer superiority over aspirin. This decrease in serious vascular events corresponds to an absolute reduction of approximately 10 to 20 per 1000 population in the yearly incidence of nonfatal events, and to a small but definite reduction in vascular-related death. An associated finding was an absolute increase in major gastrointestinal or other major extracranial bleeds, although of an order of magnitude smaller in size. For secondary prevention, then, antiplatelet therapy with aspirin has a substantial net benefit, and most patients with known cardiovascular disease should use aspirin. Use of other antiplatelet agents with demonstrated efficacy, such as clopidogrel, would be limited to patients with aspirin allergy or intolerance or those with implanted stents.

Despite the well-established role for aspirin in the secondary prevention of MI, stroke, and death from vascular causes, aspirin is substantially underprescribed in this population.⁹⁸ Data from the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey of the CDC indicate that in the period 2007 to 2008, antiplatelet medications were prescribed at only 46.9% of visits for patients with ischemic vascular disease,

unchanged from the rate for 2005 to 2006. In addition, general medicine or primary care physicians prescribed antiplatelet medication for this population only 34.8% of the time, which was actually a decrease from 37.9% in 2005 to 2006. These figures underscore the substantial lost opportunity to prevent subsequent cardiovascular disease, and the need for continued professional education in these evidence-based guidelines.

In primary prevention, however, aspirin treatment has a less clear balance of beneficial effects and bleeding hazards, because those patients without evidence of cardiovascular disease have a lower absolute risk for a cardiovascular event, with less consequent absolute benefit, whereas the risk of adverse effects remains the same. A collaborative meta-analysis of individual participant data regarding serious vascular events (MI, stroke, or vascular death) and major bleeds was published in 2009, involving six large trials of primary prevention with long-term aspirin in 95,000 patients at low-average risk, as well as 16 secondary prevention trials encompassing 17,000 patients at high-average risk for comparison.⁹⁹

In the primary prevention trials, this meta-analysis showed a statistically significant 12% reduction in serious vascular events, due primarily to a reduction of 23% in nonfatal MI. There were no significant effects on total stroke or vascular mortality. The evidence on total stroke reflected a relative reduction of 14% in risk of ischemic stroke and a 32% increased risk of hemorrhagic stroke (Fig. 42-11). As with the secondary prevention data, aspirin significantly increased risk of major gastrointestinal and extracranial bleeds. This analysis suggested a difference in aspirin's effect by sex, because aspirin reduced risk of coronary heart disease events in men but not women, whereas it had no effect on stroke in men but reduced stroke in women. These unexpected potential differences did not emerge from secondary prevention studies.⁹⁹ In the corresponding meta-analysis of secondary prevention trials, aspirin yielded greater magnitudes of reductions than in primary prevention, with significant benefits of 25% in serious vascular effects, 33% in nonfatal MI, 25% in nonfatal stroke, and 16% in vascular mortality, as well as a nonsignificant increase in hemorrhagic stroke.

An updated meta-analysis¹⁰⁰ of nine trials of aspirin for primary cardiovascular prevention with 90,000 subjects supported these results, showing statistically significant benefits for total cardiovascular events and nonfatal MI, with no significant differences in stroke, cardiovascular mortality, all-cause mortality, or total coronary heart disease.

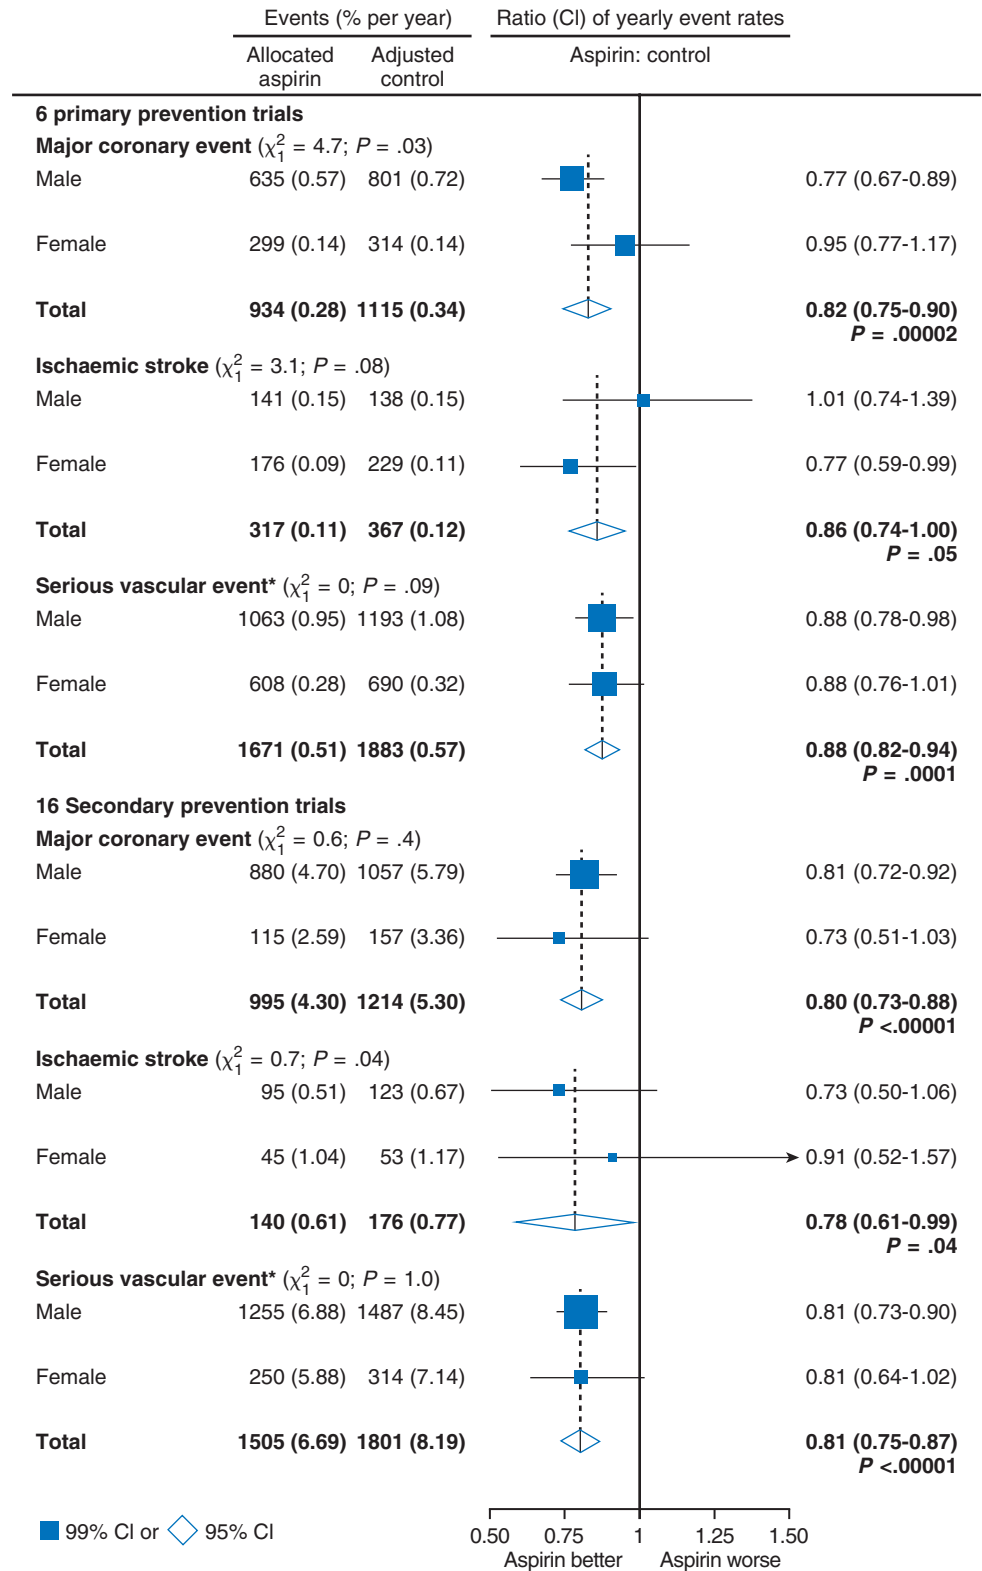

FIGURE 42-11 Selected outcomes in primary and secondary prevention trials of aspirin, by sex. CI = confidence interval. (From the Antithrombotic Trialists' (ATT) Collaboration, Baigent C, Blackwell L, et al: Aspirin in the primary and secondary prevention of vascular disease: Collaborative meta-analysis of individual participant data from randomised trials. *Lancet* 373:1849, 2009.)

The meta-analyses included three trials conducted specifically in patients with diabetes and six other trials in which patients with diabetes constituted subgroups within the study population. Together, the data suggest that aspirin appears to produce a modest-sized but not statistically significant reduction in MI and stroke in patients with

diabetes. Yet there were too few events in the available trials to permit precise estimation of either benefit or risk, and the bleeding risks of aspirin itself in diabetics require greater understanding.¹⁰¹ Two ongoing studies—ACCEPT-D (Aspirin and Simvastatin Combination for Cardiovascular Events Prevention Trial in Diabetes) and ASCEND (A Study of Cardiovascular Events in Diabetes)—should provide additional information concerning the safety and benefit profile of aspirin in patients with diabetes. In addition, trials among patients with a first episode of unprovoked venous thromboembolism have suggested a therapeutic benefit for aspirin on recurrent venous as well as arterial events after anticoagulants are discontinued, with no apparent increase in risk of major bleeding.^{102,103} Of additional note, follow-up analysis of randomized trials of daily aspirin in prevention of vascular events has shown that aspirin reduces long-term post-trial cancer deaths, including decreased incidence of and deaths from colorectal cancer observed after a delay of 8 to 10 years, and reduces risk of nonvascular death, mainly as a consequence of fewer cancer deaths after 5 years.¹⁰⁴

Taken together, these data support that compared with secondary prevention of cardiovascular disease, in which aspirin has a clear net benefit, in primary prevention, the net benefit of aspirin remains unclear, because the reduction in occlusive events must be weighed against any increase in major bleeds.¹⁰⁵ The FDA has not approved aspirin for use in primary prevention. The most recent update of the recommendations for aspirin use in primary prevention from the U.S. Preventive Services Task Force in 2009 encouraged aspirin use in men 45 to 79 years of age and in women 55 to 79 years of age if the potential benefit on a reduction in risk of MI in men and risk of ischemic stroke in women outweighs the increased risk of gastrointestinal bleeding. The use of aspirin in younger adults was not encouraged.¹⁰⁶ Taking into account the more recent meta-analyses, the European guidelines on cardiovascular disease prevention do not recommend aspirin for primary prevention because of its unfavorable risk-benefit ratio.⁴⁶ Because of the uncertainty concerning the risk-to-benefit ratio of aspirin use for patients with diabetes, the most recent recommendations specify that (1) the use of low-dose aspirin for cardiovascular prevention is reasonable for adults with diabetes and no previous history of vascular disease who are at increased cardiovascular disease risk and who are not at increased risk of bleeding; (2) aspirin should not be recommended for cardiovascular disease prevention for adults with diabetes at low risk; and (3) it might be considered for those with diabetes who are at intermediate risk.¹⁰⁷ The European guidelines, however, do not recommend aspirin use in patients with diabetes who do not have clinical evidence of atherosclerotic disease.⁴⁶ Clinicians should recognize that most data on aspirin in primary prevention predate concomitant use of statin therapy. Thus, with medical therapy instituted as an adjunct to diet, exercise, and smoking cessation, many cardiologists considering such therapy now begin with a statin rather than aspirin in primary prevention.

Conceptual Basis for the “Polypill”

In contrast with interventions that separately alter platelet function and reduce blood pressure and cholesterol, a trend has emerged in preventive intervention to consider use of “polypills.” Such pills might, for example, be formulated to contain aspirin, a statin, and an ACE inhibitor.

In secondary prevention, the use of polypill approaches has considerable advantages particularly in the developing world, where a single inexpensive intervention can provide improved delivery of care at reduced cost, and perhaps through the use of trained non-physician health care workers. This benefit has been demonstrated best in the Indian Polycap Study, where a single combined agent significantly reduced blood pressure, lipids, and overall medication compliance.¹⁰⁸ Economic analyses also suggest that multidrug polypill regimens may be cost-effective.¹⁰⁹

Substantial controversy has been documented, however, regarding the use of polypill approaches in primary prevention, where health policy, behavioral changes, and population-based interventions

compete for resources with individual-level interventions.¹¹⁰ On the basis of epidemiologic modeling, advocates have suggested that combination pills could reduce vascular event rates in this setting by 75% to 80%, although trial data demonstrating such effects do not yet exist. Considerable controversy persists as to what specific agents should be included in polypill combinations, and whether large numbers of individuals should receive certain interventions such as aspirin or antihypertensive therapy without previous screening. A recent trial of a four-component combination pill in primary prevention demonstrated significant reductions in blood pressure and cholesterol when compared with placebo, but the polypill had high discontinuation rates and produced a significant excess of side effects.¹¹¹ Nonetheless, ongoing trials should merit close attention, because the conceptual basis of providing combination therapy as an adjunct to lifestyle interventions is sound, and such therapy is a potentially effective method of achieving broad compliance with proven classes of preventive medications.

NONCONVENTIONAL RISK MARKERS AND ASSOCIATED INTERVENTIONS

Despite the importance of blood lipids, 50% of all MIs occur in persons without overt hyperlipidemia. In a major prospective study of healthy American women, 77% of all future cardiovascular events occurred in patients with LDL cholesterol levels less than 160 mg/dL and 46% occurred in those with LDL cholesterol levels less than 130 mg/dL.¹¹² Although the use of global prediction models such as those developed in Framingham greatly improves the detection of heart disease risk, because many as 20% of all events occur in the absence of any of the major classic vascular risk factors.

This fact challenges several basic issues related to current screening programs for risk detection and disease prevention, and clinical data continue to accrue demonstrating the hazard of relying solely on classic risk factors. In one analysis of more than 120,000 patients with coronary heart disease, 15% of women and 19% of men had no evidence of hyperlipidemia, hypertension, diabetes, or smoking and more than 50% had only one of these general risk factors.¹¹³ In another large analysis, between 85% and 95% of participants with coronary disease had at least one conventional risk factor, but so too did those participants without coronary disease evaluated over a follow-up period of up to 30 years.¹¹⁴ Thus, because of the considerable need to improve vascular risk detection, much research over the past 10 to 15 years has focused on the identification and evaluation of novel atherosclerotic risk factors.

When evaluating any novel risk factor as a potential new screening tool, clinicians need to consider (1) whether there is a standardized and reproducible assay for the biomarker of interest; (2) whether there is a consistent series of prospective studies demonstrating that a given parameter predicts future risk; (3) whether the novel marker adds to the predictive value of lipid screening; (4) whether there is evidence that the novel marker adds to global risk prediction scores, such as that in the Framingham Heart Study; and (5) whether knowledge of the biomarker would lead to a proven intervention to reduce risk that the patient otherwise would not have received. (See Chapter 10 for a detailed discussion of quantitative approaches to answering these questions.) Presented next are these basic epidemiologic requirements as applied to a series of novel risk factors, including hsCRP and other markers of inflammation, Lp(a), and homocysteine. Physicians also should consider the relative magnitude of novel markers in terms of risk prediction, particularly in comparison with lipid screening.

High-Sensitivity C-Reactive Protein

Inflammation characterizes all phases of atherothrombosis and provides a critical pathophysiologic link between plaque formation and acute rupture, leading to occlusion and infarction. Formation of the fatty streak, the earliest phase of atherogenesis, involves recruitment of leukocytes mediated by the expression of adhesion molecules on

endothelial cells, in turn triggered by inflammatory cytokines such as IL-1 and tumor necrosis factor. Subsequent migration of inflammatory cells into the subendothelial space requires chemotaxis controlled by chemokines induced by the primary cytokines. Mononuclear cells within this initial infiltrate, as well as intrinsic vascular cells, subsequently release growth factors that stimulate proliferation of the smooth muscle cells and lead to plaque progression. The thrombotic complications of plaques often involve physical disruption, usually associated with signs of local and systemic inflammation. Other proinflammatory cytokines such as CD40 ligand can in turn induce tissue factor expression and promote thrombus formation. Moreover, the primary proinflammatory cytokines effect the expression of messenger cytokines such as IL-6, which can travel from local sites of inflammation to the liver, where a change in the program of protein synthesis characteristic of the acute phase response is thereby triggered (see Chapter 41).

In clinical practice, the best-studied and most easily applied biomarker of this inflammatory process is the acute-phase reactant CRP. Composed of five 23-kDa subunits, CRP, a circulating member of the pentraxin family, functions in the human innate immune response. Although derived primarily from the liver, studies have found that cells within human coronary arteries, particularly in the atherosclerotic intima, can also elaborate CRP. Whether CRP simply marks inflammatory risk, or has a direct role in the atherothrombotic process, remains controversial.

Regardless of whether CRP has a causal role, a consistent series of large-scale prospective cohorts conducted worldwide indicate that CRP, when measured with high-sensitivity assays (hsCRP), independently predicts risk of MI, stroke, peripheral arterial disease, and sudden cardiac death among apparently healthy persons, even when LDL cholesterol levels are low.¹¹⁵ In recent comprehensive meta-analyses, the multivariable hazard associated with hsCRP, if anything, exceeded that associated with either blood pressure or cholesterol¹¹⁶ (Fig. 42-12). Furthermore, as recently demonstrated in the Emerging Risk Factors Collaboration, hsCRP yielded an increment in the C-statistic in terms of predicting future coronary heart disease events virtually identical in magnitude to that of total and HDL cholesterol¹¹⁷ (Fig. 42-13). Most important, of emerging biomarkers, only hsCRP adds prognostic information at all levels of LDL cholesterol and at all levels of risk, as determined by the Framingham risk score. Because hsCRP levels reflect a component of vascular risk different from that of cholesterol, the addition of hsCRP to lipid evaluation provides a major new opportunity to improve cardiovascular prediction and prevention. In clinical terms, individuals with elevated hsCRP levels and low levels of LDL cholesterol actually have higher absolute vascular risk than do those with elevated levels of LDL cholesterol but low levels of hsCRP¹¹² (Fig. 42-14).

The American Heart Association (AHA) and the CDC issued the first guidelines for the use of hsCRP levels in clinical practice in 2003. Briefly stated, hsCRP levels of less than 1, 1 to 3, and higher than

FIGURE 42-12 The magnitude of independent risk associated with a 1-SD change in hsCRP is at least as large as a comparable 1-SD change in blood pressure (BP) and lipid levels. HDLC = high-density lipoprotein cholesterol. (Modified from Emerging Risk Factors Collaboration, Kaptoge S, Di Angelantonio E, et al: C-reactive protein concentration and risk of coronary heart disease, stroke, and mortality: An individual participant meta-analysis. *Lancet* 375:132, 2010.)

3 mg/liter should be interpreted as lower, moderate, and higher relative vascular risk, respectively, when considered along with traditional markers of risk. Application within the Framingham Heart Study itself recently has corroborated this critical finding.¹¹⁸ Screening for hsCRP should be done at the discretion of the physician as part of global risk evaluation, not as a replacement for LDL and HDL testing. Although hsCRP predicts risk across the entire population

FIGURE 42-13 The magnitude of change in the C-statistic associated with the addition of hsCRP to global risk prediction models is fully comparable with that associated with total and HDL cholesterol. TC = total cholesterol. (Modified from Emerging Risk Factors Collaboration, Kaptoge S, Di Angelantonio E, et al: C-reactive protein, fibrinogen, and cardiovascular disease prediction. *N Engl J Med* 367:1310, 2012.)

FIGURE 42-14 Cardiovascular event free survival among apparently healthy persons according to baseline levels of hsCRP and LDL cholesterol. (From Ridker PM, Rifai N, Rose L, et al: Comparison of C-reactive protein and low density lipoprotein cholesterol levels in the prediction of first cardiovascular events. *N Engl J Med* 347:1557, 2002.)

spectrum, it is likely to be of greatest usefulness in patients at intermediate risk—that is, those with anticipated 10-year event rates between 5% and 20%. After publication of this recommendation, the 2009 guidelines from the Canadian Cardiovascular Society endorsed evaluation of hsCRP among persons classified as being at “intermediate risk.”¹¹⁹ The 2011 guidelines from the National Lipid Association recommend “routine” use of hsCRP in this primary prevention group, the only biomarker other than LDL cholesterol and HDL cholesterol to receive this designation.⁷⁵ Values of hsCRP in excess of 8 mg/liter may represent an acute-phase response caused by an underlying inflammatory disease or intercurrent infection and should lead to repeat testing in approximately 2 to 3 weeks. Because hsCRP levels have equivalent stability over long periods to that of traditional risk factors, exhibit minimal circadian variation, and do not depend on prandial state, outpatients can readily undergo screening at the time of cholesterol evaluation.

In clinical practice, many physicians now use both hsCRP and family history as part of global risk prediction. The freely available Reynolds risk scores facilitate this process (www.reynoldsrisk.com).¹²⁰ In several independent cohorts, the Reynolds risk score has proved to have superior discrimination and calibration than the Framingham risk score¹ and provides improved predictive information for vascular disease progression.¹²¹ Levels of hsCRP greater than 3 mg/liter also predict recurrent coronary events, thrombotic complications after angioplasty, poor outcome in the setting of unstable angina, and vascular complications after bypass surgery. All of these data support the concept that inflammation plays a critical role throughout the atherothrombotic process. Additionally, hsCRP has prognostic usefulness in cases of acute ischemia, even without troponin level elevation, suggesting that an enhanced inflammatory response at the time of hospital admission can determine subsequent plaque rupture. These findings help explain why persons with elevated hsCRP levels are likely to accrue greater benefit from aggressive interventions compared with those with low hsCRP levels. This marker also is associated with vascular events and ischemic episodes in patients with “syndrome X” who have no other risk factors and an absence of angiographic disease—evidence suggesting a role for inflammation in coronary microvascular function.

Levels of hsCRP correlate only modestly with underlying atherosclerotic disease as measured by carotid intimal medial thickness or by coronary calcification. This observation suggests that hsCRP does not simply reflect the presence of subclinical disease but indicates an increased propensity for plaque disruption and/or thrombosis. Autopsy data support this hypothesis: Elevated hsCRP levels are more common in patients with frankly ruptured plaques than in those with erosive disease or those who died of nonvascular causes. In patients with other conditions, such as allograft atherosclerosis and chronic renal failure and dialysis, hsCRP levels have strong predictive value for poor short-term and long-term cardiovascular outcomes. Elevated levels of hsCRP predict not only cardiovascular events but also the onset of type 2 diabetes, perhaps because hsCRP levels correlate with several components of the metabolic syndrome, including those not easily measured in clinical practice such as insulin sensitivity, endothelial dysfunction, and hypofibrinolysis. As discussed earlier in the section on insulin resistance and diabetes, hsCRP assessment also adds prognostic information at all levels of the metabolic syndrome.

Interventions for Primary Prevention in Patients with Elevated High-Sensitivity C-Reactive Protein Levels

As in the case for those with elevated LDL cholesterol, diet, exercise and smoking cessation are the first-line interventions for those with elevated hsCRP. At a minimum, an elevated hsCRP level should provide considerable motivation to improve lifestyle, particularly for those previously told that they were not at risk because of an absence of hyperlipidemia.

Beyond lifestyle change, the use of statin therapy to reduce vascular risk among individuals with elevated hsCRP, even with low LDL cholesterol levels, represents a fundamental change in treatment strategies for the prevention of cardiovascular disease. Most importantly, in the JUPITER trial⁸ in apparently healthy men and women

with LDL cholesterol levels less than 130 mg/dL who were at increased risk because of hsCRP levels of 2 mg/L or greater, the use of rosuvastatin resulted in a 44% reduction in the trial primary endpoint of all vascular events ($P < .000001$), a 54% reduction in MI ($P = .0002$), a 48% reduction in stroke ($P = .002$), a 46% reduction in need for arterial revascularization ($P < .001$), and a 20% reduction in all-cause mortality ($P = .02$) (Fig. 42-15). All prespecified subgroups within JUPITER significantly benefited from statin therapy including those previously considered to be at “low risk” such as women, nonsmokers, those without metabolic syndrome, and those with Framingham scores less than 10%. From a public policy perspective, the 5-year number needed to treat (NNT) within JUPITER was only 25, a value smaller than the comparable 5-year NNT associated with the treatment of hyperlipidemia or hypertension in primary prevention. In an additional prespecified analysis, rosuvastatin reduced incident venous thromboembolism by 43%, a result with clinical relevance and an important observation regarding pleiotropic effects of statin therapy.¹²² As described earlier, these vascular benefits outweigh the small hazard of diabetes associated with statin use.

The JUPITER trial also demonstrates that achieving low levels of both LDL cholesterol and hsCRP after the initiation of statin therapy might maximize preventive efforts, at least with statin therapy. Within the JUPITER cohort, those who not only reduced LDL cholesterol to less than 70 mg/dL but also reduced hsCRP to below 1 mg/L had an 80% reduction in risk¹²³ (Fig. 42-16). This observation made in a primary prevention setting extends prior work in high-risk secondary prevention demonstrating the benefit of achieving “dual goals” for both LDL cholesterol and hsCRP.¹²⁴ For example, in the Pravastatin or Atorvastatin Evaluation and Infection Therapy–Thrombolysis in Myocardial Infarction 22 (PROVE IT–TIMI 22) trial, conducted in patients with acute coronary syndromes treated with statin therapy, achieving levels of hsCRP less than 2 mg/liter conferred equivalent long-term event-free survival as achieving levels of LDL cholesterol less than 70 mg/dL; indeed, those who met both of these goals enjoyed the best long-term outcomes¹²⁵ (Fig. 42-17). Coronary atheromata can actually regress with statin therapy among those with CRP reduction.¹²⁶ The JUPITER trial also provides data demonstrating the efficacy of statin therapy in women¹²⁷ and elderly persons¹²⁸ and in the primary prevention of stroke.¹²⁹ Economic analyses affirm the cost-effectiveness of statin therapy for primary prevention patients with elevated hsCRP.¹³⁰

Although inflammation participates in vascular injury and hsCRP provides an inexpensive and clinically useful measure of this process, the stimulus that initiates the underlying proinflammatory response remains uncertain. Patients with chronic inflammatory diseases such as rheumatoid arthritis, inflammatory bowel disease, and psoriasis tend to have elevated hsCRP levels and, on average, are at somewhat higher vascular risk, but a causal relationship in this setting has been difficult to establish. Patients with low-grade infections such as gingivitis or those who are chronic carriers of *Chlamydia pneumoniae*, *Helicobacter pylori*, herpes simplex virus, and cytomegalovirus also may have a higher risk for vascular problems on the basis of a chronic systemic inflammatory response. Yet, careful prospective studies of antibody titers directed against these agents have not consistently found evidence of association, and large-scale antibiotic trials have not shown reduced event rates.

Although the JUPITER trial demonstrated the efficacy of statin therapy among those with elevated hsCRP even when LDL cholesterol levels are low, it is unknown whether lowering CRP per se could in turn reduce vascular event rates. Early “mendelian randomization” analyses have not supported a direct causal role for CRP in atherothrombosis, but more recent studies of this type endorse a causal role for related IL-6 pathways.¹³¹ These data strongly support ongoing “cardiovascular inflammation reduction trials” such as those evaluating low-dose methotrexate and the novel IL-1 β inhibitor canakinumab.¹³²

Other Biomarkers of Inflammation

Although hsCRP currently is the best-characterized inflammatory biomarker for clinical use, several other markers of inflammation

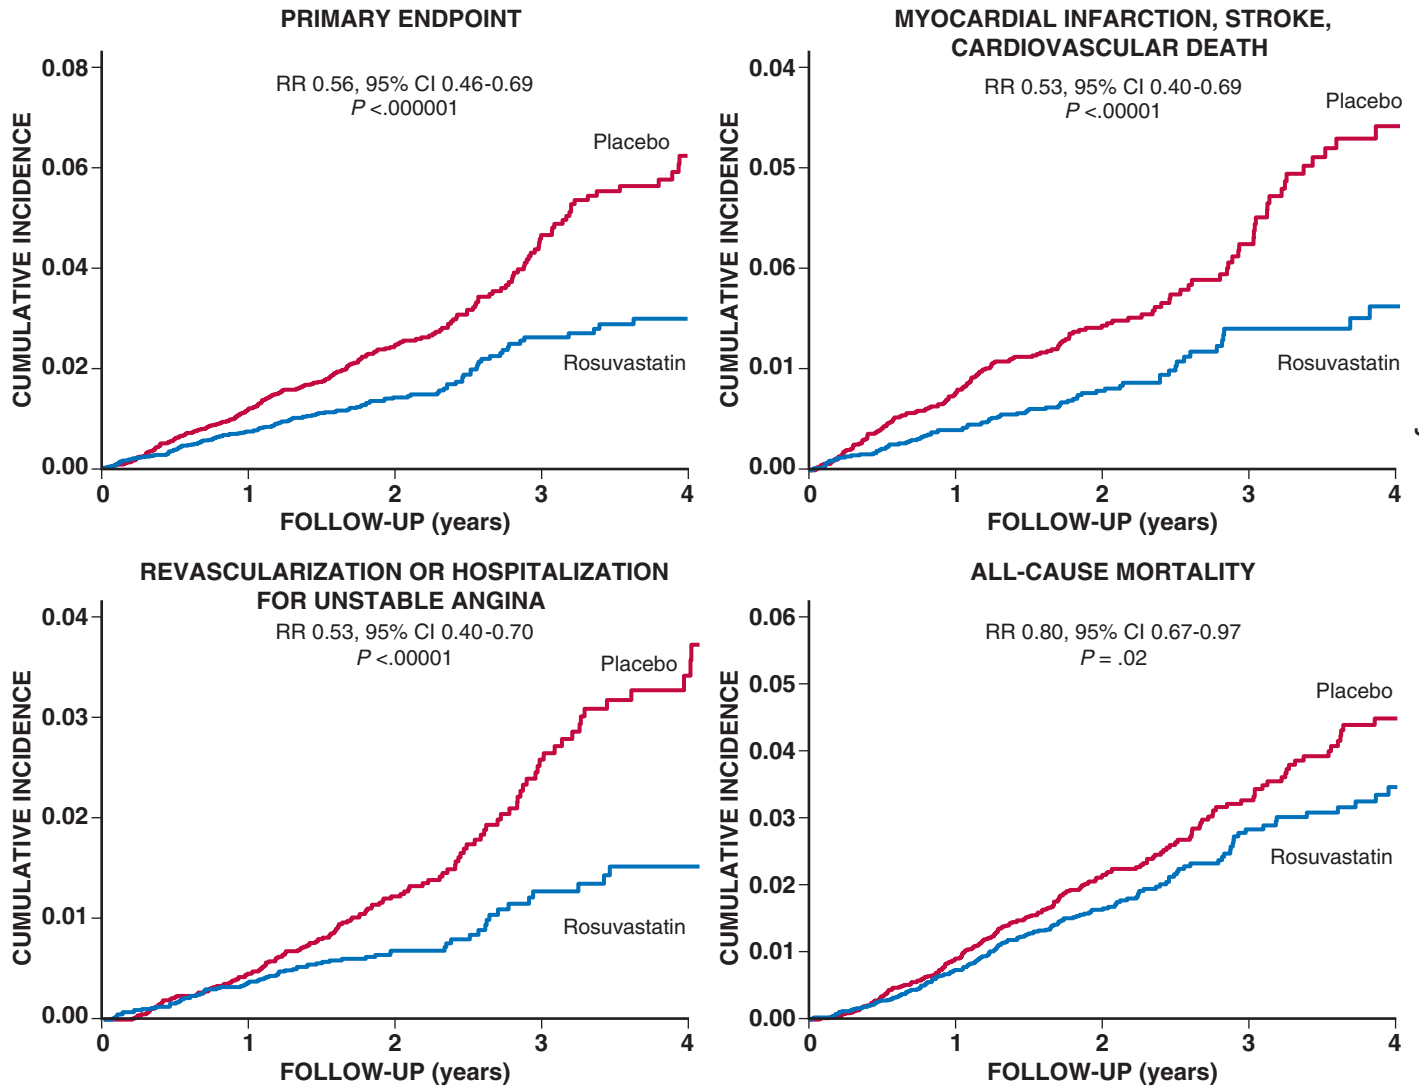

FIGURE 42-15 Primary results of the JUPITER trial of statin therapy among healthy men and women with LDL cholesterol less than 130 mg/dL and hsCRP greater than 2 mg/L. (Modified from Ridker PM, Danielson E, Fonseca FA, et al: Rosuvastatin to prevent vascular events in men and women with elevated C-reactive protein. *N Engl J Med* 359:2195, 2008.)

FIGURE 42-16 Incident cardiovascular events in the JUPITER trial according to concentrations of LDL cholesterol and hsCRP achieved after initiation of statin therapy. (From Ridker PM, Danielson E, Fonseca FA, et al: Reduction in C-reactive protein and LDL cholesterol and cardiovascular event rates after initiation of rosuvastatin: A prospective study of the JUPITER trial. *Lancet* 373:1175, 2009.)

have shown promise in predicting vascular risk and provide further insights into the role played by inflammation in atherothrombosis. These include cytokines such as IL-1 and IL-6, soluble forms of certain cell adhesion molecules such as intercellular adhesion molecule (sICAM-1), P-selectin, and the mediator CD40 ligand, as well as markers of leukocyte activation such as myeloperoxidase, pregnancy-associated plasma protein A, and the IL-1 receptor family member ST2. Unfortunately, many of these alternative inflammatory biomarkers have analytic limitations that to date have reduced clinical usefulness. For example, some have too short a half-life for clinical diagnostic testing, and the ability of others to predict risk in settings of broad populations has proved to be marginal thus far. Nonetheless, measurement of several of these inflammatory biomarkers can shed critical pathophysiologic light on the atherothrombotic process, particularly at the time of plaque rupture. For example, soluble CD40 ligand (probably released from activated platelets) may provide insight into the efficacy of specific antithrombotic agents independently of CRP. Similarly, myeloperoxidase may provide prognostic information in cases of acute ischemia over and above that associated with troponin or CRP, whereas clinical studies with ST2 indicate novel associations in heart failure and ischemia.¹³³

Although also an acute phase reactant and thus often considered an inflammatory biomarker, plasma fibrinogen additionally influences platelet aggregation and blood viscosity, interacts with plasminogen binding and, in combination with thrombin, mediates the final step in clot formation and the response to vascular injury. Fibrinogen levels have a positive association with age, obesity, smoking, diabetes, and LDL cholesterol level and a negative association with HDL cholesterol level, alcohol use, physical activity, and exercise level.

Given these relationships, it is not surprising that fibrinogen was among the first “novel” risk factors evaluated. Early reports from the Gothenburg, Northwick Park, and Framingham heart studies all found significant positive associations between fibrinogen levels and future risk of cardiovascular events. Since then, a number of other prospective studies have confirmed these findings, and in meta-analyses, an approximately linear logarithmic association was seen between usual fibrinogen level and the risk of coronary heart disease and stroke.¹³⁴ In recent studies, hsCRP and fibrinogen levels showed additive ability to predict risk, although hsCRP appeared to have a larger absolute effect. This observation is of particular interest because CRP and fibrinogen have distinct genetic determinants. Other studies have suggested that fibrinogen has the highest

predictive usefulness in patients with other concomitant elevations of Lp(a) or homocysteine. Despite the consistency of these data, measurement of fibrinogen has found limited use in clinical practice because of suboptimal assay standardization and inconsistency across reference laboratories.

Other than hsCRP, the only inflammatory biomarker commercially available is Lp-PLA₂. As with hsCRP, most—but not all—published studies indicate a positive relationship between Lp-PLA₂ and vascular risk. In contrast with hsCRP, however, Lp-PLA₂ circulates bound to lipoproteins such as apo B, so its levels strongly correlate with LDL cholesterol. Because of this effect, adjustment for lipid levels largely attenuates the strength of association between Lp-PLA₂ and vascular events, making contributions to risk detection small.⁷² Clinically, the availability of both mass and activity assays, each with suboptimal reproducibility, has further complicated the evaluation of Lp-PLA₂. In two recent large-scale trials, Lp-PLA₂ no longer predicted residual risk after aggressive LDL cholesterol reduction with statin therapy.^{135,136} Accordingly, expert reviews have suggested that the measurement of Lp-PLA₂ is rarely warranted for most patients.¹³⁷ As described further on, however, Lp-PLA₂ provides a target for intervention worthy of testing.

Interventions to Reduce Alternative Markers of Inflammation

To date, four clinical trials have evaluated the potential benefits of fibrinogen reduction and all have found disappointing results. Specifically, two trials of bezafibrate have shown no reduction in event rates with active therapy despite significant reductions in fibrinogen levels. Similarly, in the Heart and Estrogen/Progestin Replacement Study (HERS) and in the WHI, hormone replacement therapy lowered fibrinogen but did not improve clinical outcomes.

At this time, several major multinational trials are evaluating whether specific agents that directly or indirectly target inflammation can reduce vascular event rates. Therapies under evaluation include darapladib (an inhibitor of Lp-PLA₂), canakinumab (a monoclonal antibody targeting IL-1 β), and the generic anti-inflammatory agent low-dose methotrexate (LDM), already in wide use for the treatment of rheumatoid arthritis. Darapladib does not reduce CRP or IL-6 and therefore may not formally qualify as an “anti-inflammatory” intervention. By contrast, LDM or canakinumab reduce multiple intermediary inflammatory biomarkers without altering lipid levels. Thus trials of these latter agents provide an unconfounded direct test of the inflammation hypothesis of atherothrombosis.¹³⁸

FIGURE 42-17 Cumulative rate of recurrent myocardial infarction or death in statin-treated patients according to both levels of LDL cholesterol and hsCRP after 30 days of therapy in the PROVE IT TIMI-22 trial. (From Ridker PM, Cannon CP, Morrow D, et al: C-reactive protein levels and outcomes after statin therapy. *N Engl J Med* 352:20, 2005.)

Lipoprotein(a)

Lp(a) (see also Chapters 45 and 82) consists of an LDL particle with its apo B100 component linked by a disulfide bridge to apolipoprotein(a) [apo(a)], a variable-length protein that has sequence homology to that of plasminogen. The apo(a) component of Lp(a) is a complex molecule composed in part of a variable number of cysteine-rich kringle IV repeats that result in great heterogeneity. Accordingly, plasma Lp(a) concentrations vary inversely with apo(a) isoform size but also may vary even in isoform size, based on differential levels of production. Underlying its molecular complexity, more than 25 heritable forms of Lp(a) exist, demonstrating the importance of the genome in determining plasma levels, an important issue for risk prediction across different population groups. The close homology between Lp(a) and plasminogen has raised the possibility that this lipoprotein may inhibit endogenous fibrinolysis by competing with plasminogen binding on the endothelium. More recent studies have suggested that Lp(a) binds and inactivates tissue factor pathway inhibitor and may augment the expression of plasminogen activator inhibitor, further linking lipoproteins and thrombosis. Lp(a) also colocalizes within atherosclerotic lesions and may have local actions through oxidized phospholipids pathways. Thus several mechanisms may contribute to a role for Lp(a) in atherothrombosis.

In an updated meta-analysis of 36 prospective studies that included more than 12,000 cardiovascular endpoints, the adjusted risk ratios for each SD increase in plasma Lp(a) level were 1.13 for coronary

heart disease and 1.10 for ischemic stroke.¹³⁹ Adjustment for classic cardiovascular risk factors only modestly attenuated these effects, in part because Lp(a) and other markers of risk show little correlation. Whether the assessment of Lp(a) truly adds prognostic information to overall risk in primary prevention remains uncertain, however, because in most studies, Lp(a) typically has proved to be predictive for persons already known to be at high risk because of the presence of other risk factors, in particular, elevated levels of LDL cholesterol. Several prospective evaluations have shown that Lp(a) predicts risk nonlinearly, with risk increasing only slightly until Lp(a) levels reach the top 5th to 10th percentile.¹⁴⁰ Some investigators have advocated Lp(a) assessment in certain patient groups, such as those with established coronary disease or renal failure, although data remain controversial. Evidence that children with recurrent ischemic stroke have elevated Lp(a) levels also supports the potential use of this biomarker in unusual high-risk settings.

Standardization of commercial Lp(a) assays remains challenging, and inaccuracy of commercial Lp(a) assays has resulted from the use of techniques sensitive to apo(a) size. At present, most reference laboratories have available commercial assays that measure Lp(a) in a manner independent of apo(a) isoform size. Using one such assay, investigators in the Women's Health Study found that extremely high levels of Lp(a) (greater than the 90th percentile, or higher than 65.6 mg/liter) indeed are associated with increased cardiovascular risk, independent of other traditional risk factors.¹⁴¹ This risk increase was nonlinear and limited to those patients with concomitant elevations of LDL cholesterol levels, confirming earlier work. Thus the presence of threshold effects and interactions with LDL cholesterol limit the routine measurement of Lp(a) for cardiovascular risk stratification in the general population.

Interventions to Reduce Lipoprotein(a)

With the exception of high-dose niacin, few approved interventions lower Lp(a) level, and no study to date has shown that Lp(a) reduction lowers vascular risk. This limitation, as well as the observation that LDL cholesterol reduction markedly reduces the hazard associated with Lp(a), has also dampened enthusiasm for screening. Genetic investigations have provided important insights into Lp(a) regulation, however, and they suggest a causal relationship between Lp(a) and increased risk.^{142,143} Furthermore, new agents—such as mipomersen, PCSK9 inhibitors, and anacetrapib—that markedly reduce apo B levels, appear to reduce Lp(a) significantly. Thus continued development of therapies that inhibit Lp(a) merit consideration and direct testing in clinical trials. In one recent pharmacogenetic study, the benefit of prophylactic aspirin linked closely to specific genetic polymorphisms associated with Lp(a) expression. If effective therapy for Lp(a) were available and proved to reduce vascular risk, then screening among higher-risk patients might become warranted.

Homocysteine

Homocysteine is a sulfhydryl-containing amino acid derived from the demethylation of dietary methionine. In patients with rare inherited defects of methionine metabolism, severe hyperhomocysteinemia (plasma levels higher than 100 mmol/liter) can develop; such patients are at markedly elevated risk for premature atherothrombosis as well as venous thromboembolism. Mechanisms suggested to account for these effects include endothelial dysfunction, accelerated oxidation of LDL cholesterol, impairment of flow-mediated endothelium-derived relaxing factor with subsequent reduction in arterial vasodilation, platelet activation, and oxidative stress. In contrast with severe hyperhomocysteinemia, mild to moderate elevations of homocysteine (plasma levels higher than 15 mmol/liter) are more common in the general population, primarily because of insufficient dietary intake of folic acid. Other patient groups in which elevated levels of homocysteine are likely include those receiving folate antagonists such as methotrexate and carbamazepine and those with impaired homocysteine metabolism caused by hypothyroidism or renal insufficiency.

A common polymorphism in the methylene tetrahydrofolate reductase gene (*MTHFR*) that encodes a thermolabile protein also links to elevated homocysteine levels and to increased vascular risk, at least among persons homozygous for the variant. Familial association studies have reported higher homocysteine levels in offspring of parents with premature coronary artery disease. The clinical importance of the *MTHFR* polymorphism appears to be modest, however, and heterozygous persons display little evidence of elevated homocysteine levels, even in those with low folate intake. In a meta-analysis of 40 observational studies, patients homozygous for the *MTHFR* 677 TT variant had a 16% increase in relative risk (odds ratio, 1.16; 95% CI, 1.05 to 1.28), and this observation was evident only in studies originating in Europe.¹⁴⁴ In populations in which folate fortification exists, such as in North America, no compelling evidence supports genetic evaluation of *MTHFR* to predict vascular risk. For example, in the large-scale Women's Health Study, *MTHFR* variants associated with plasma homocysteine levels, which in turn were associated with modest elevation of risk, showed no independent effect of the gene variants on clinical outcomes.¹⁴⁵

Reliable immunoassays for total plasma homocysteine (the combination of free homocysteine, bound homocysteine, and mixed disulfides), now widely available, have largely replaced the use of high-performance liquid chromatography. Despite the availability of newer assays, measurement of homocysteine remains controversial, and recent guidelines have not advocated their use. This lack of enthusiasm reflects modest overall effects reported in prospective cohort studies and the publication of several large trials of homocysteine reduction. With regard to epidemiologic evidence, although there is some heterogeneity between prospective studies, on average a 25% lower homocysteine level appears to be associated with an approximate 11% lower risk of coronary heart disease. At least in the United States, however, fortification of the food supply has greatly reduced the frequency of low folate and elevated homocysteine levels, particularly for persons with values initially in the moderately elevated range. Thus the number of patients potentially identifiable by screening for homocysteine has decreased considerably.

Interventions to Reduce Homocysteine

With regard to clinical trials of homocysteine reduction, several major studies have been completed and none have shown substantive benefit. The Vitamin Intervention for Stroke Prevention (VISP) trial, conducted among 3680 patients with prior stroke allocated to high-dose or low-dose vitamin regimens containing folate and pyridoxine, showed no evidence of differential benefit in the high-dose group, despite greater homocysteine level reduction.¹⁴⁶ The Norwegian Vitamin Trial (NORVIT) involving 3749 participants with recent MI showed a net harmful effect associated with combined vitamin B supplementation. In that trial, mean total homocysteine fell by 27% in the intervention group; this drop did not yield a significant effect on the primary endpoint (hazard ratio [HR], 1.08; 95% CI, 0.93 to 1.25) but rather demonstrated a trend toward increased risk in those patients allocated to receive folate, vitamin B₆, and vitamin B₁₂ (HR, 1.22; 95% CI, 1.00 to 1.50).¹⁴⁷ Similarly, in the Heart Outcomes Prevention Evaluation (HOPE-2) trial of 5522 patients with vascular disease or diabetes, 5 years of therapy with folate, vitamin B₆, and vitamin B₁₂ resulted in no benefit compared with placebo for total vascular events (HR, 0.95; 95% CI, 0.84 to 1.07), cardiovascular mortality (HR, 0.96; 95% CI, 0.81 to 1.13), or any of several prespecified secondary endpoints.¹⁴⁸ Finally, in a major Department of Veterans Affairs trial including 2056 patients with advanced renal disease, treatment with high doses of folic acid and B vitamins did not improve survival nor reduce incidence of vascular events.¹⁴⁹ As a group, these consistently negative trial results conflict with the supposition made from studies of mendelian randomization that had previously argued for a clear causal role between homocysteine concentration and vascular events.¹⁵⁰

Despite reduced enthusiasm and lack of evidence that homocysteine reduction lowers risk, there remain specific patient populations for whom homocysteine evaluation may prove appropriate, including those lacking traditional risk factors, with renal failure, or with

markedly premature atherosclerosis or a family history of MI and stroke at a young age.¹⁵¹ Continuing folate supplementation in the general population is also crucial, to reduce the risk of neural tube defects—an inexpensive practice that has been in place in the United States for more than a decade, yet remains a public health challenge for much of Europe and the developing world.

Direct Plaque Imaging

In contrast with biologic factors that predispose to disease, direct imaging of preclinical atherosclerosis provides an alternative method to detect high-risk individuals who might benefit from early preventive interventions. Although several novel imaging tests are in development, the best studied to date are ultrasound measures of the common carotid intima-media thickness (CIMT) and computed tomography to detect coronary artery calcification (CAC). Both of these imaging modalities can detect high-risk individuals, yet both have engendered controversy in preventive practice.¹⁵² For example, with regard to CIMT, a recent meta-analysis of 14 population-based cohorts reported a consistent and statistically significant 9% increase in future vascular risk for each 0.1-mm increase in CIMT thickness; however, that same analysis found CIMT of unlikely clinical importance once risk estimates and reclassification underwent adjustment for usual risk factors.¹⁵³ The Framingham investigators also have recently reported limited usefulness for CIMT in risk prediction.¹⁵⁴

To date, multiple studies have shown increased levels of CAC to strongly predict vascular risk, and advocates of this approach correctly note that unlike CIMT, CAC can provide substantial reclassification in primary prevention. Both the Heinz Nixdorf Recall Study¹⁵⁵ and recent analyses from the Multi-Ethnic Study of Atherosclerosis (MESA) have shown that CAC, ankle-brachial index, hsCRP levels, and family history (but not CIMT) independently predict incident vascular events among persons at “intermediate risk.”¹⁵⁶ CAC scanning, however, causes radiation exposure and results in increased downstream testing consequent to unanticipated false-positive

findings. Whether CAC can cost-effectively improve prevention also remains highly controversial. Moreover, CAC has had a quite limited impact on changing patient or physician behavior with regard to preventive interventions.¹⁵⁷

Part of the difficulty with coronary calcification as a clinical biomarker is that CT imaging probably detects the plaques least likely to rupture and does not detect the noncalcified thin-capped lesions that appear to cause most clinical events. Thus, although coronary calcium provides a noninvasive measure of atherosclerotic burden, patients with low calcium scores cannot be dismissed as being at low risk. In one study of currently asymptomatic individuals, 41% of all future vascular events occurred in those with a coronary artery calcium score (CACS) less than 100, and 17% occurred in those with a CACS of 0.¹⁵⁸ Furthermore, in this study, those with high Framingham risk scores but low coronary calcium scores remained at high risk. Thus the absence of CAC does not preclude occurrence of coronary events over longer-term follow-up.

Over the next decade, imaging of atherosclerosis will likely extend beyond anatomic evaluation, to focus instead on functional properties that define vascular inflammation and unstable plaque.¹⁵⁹ Such studies are already ongoing and exploit the ability of different imaging modalities and selective imaging probes to detect molecular and microanatomic targets that have specificity for plaque rupture. In part, the impetus for this new research stems from recognition that “stable” plaques with a fibrotic morphology have relatively low rupture rates, whereas plaques with inflammatory activity have a higher likelihood of causing vascular events, even though both look similar on current macroanatomic imaging. Potential new targets for this functional imaging approach include measures of glucose uptake, specific adhesion molecules, and biomarkers of apoptosis and protein degradation (Fig. 42-18). Magnetic resonance imaging (MRI), positron emission tomography (PET), and contrast-enhanced ultrasonography—each linked to specific molecular targets—all are now under investigation, as are functional measures of vascular reactivity such as coronary flow reserve.

FIGURE 42-18 Novel targets for noninvasive vascular imaging of the atherosclerotic plaque. MMPs = matrix metalloproteinases. (From Camici PG, Rimoldi OE, Gaemperli O, Libby P: Non-invasive anatomic and functional imaging of vascular inflammation and unstable plaque. *Eur Heart J* 33:1309, 2012.)

Interventions Based on Vascular Imaging

A major limitation of all imaging modalities is that, unlike the situation for plasma biomarkers such as LDL cholesterol or hsCRP, no outcome trials demonstrate that patients identified by any imaging biomarker of interest benefit from a therapy they otherwise would not have received. The recent Detection of Ischemia in Asymptomatic Diabetics (DIAD) trial underscores the importance of performing such trials. In DIAD, random allocation to ischemia screening with myocardial perfusion imaging failed to reduce incident MI, vascular death, or episodes of ischemia during follow-up.¹⁶⁰ Furthermore, scant evidence exists that imaging improves general preventive measures; in the recent randomized Early Identification of Subclinical Atherosclerosis by Noninvasive Imaging Research (EISNER) trial, knowledge of CAC failed to improve rates of smoking cessation or exercise and had no impact on total cholesterol, HDL cholesterol, triglycerides, glucose, body weight, or adherence to preventive medicines including statins or aspirin.¹⁵⁷ Thus, in view of issues of cost (and, in some cases, radiation exposure), the expanded use of imaging as a screening tool for vascular risk detection in the setting of primary prevention should await substantive work, including hard-outcome trials.¹⁶¹

Genetic Markers for Cardiovascular Risk

Heritability accounts for up to half of the susceptibility to coronary heart disease (see also Chapter 8). Yet, until very recently, genetic risk factors predisposing to heart disease were difficult to quantify. This situation has markedly changed with the advent of very large-scale genome-wide association studies (GWASs) capable of defining small but highly significant risks for individual single-nucleotide polymorphisms (SNPs) common in the general population.¹⁶² In the

Global Lipids Genetics Consortium,¹⁶³ for example, which included more than 100,000 persons of European descent, 95 genetic loci were described that contribute both to normal lipid variation and to extreme lipid phenotypes. Other informative GWASs have focused on inflammatory phenotypes such as CRP and the IL-6 receptor pathway, the latter suggesting a causal role of inflammation in the atherothrombotic process.¹³¹ The genomic locations of variants directly associated with risk of MI and heart failure localize across the human genome¹⁶⁴ (Fig. 42-19).

Several important observations derive from these accumulating data. First, although some genetic variants mediate risk through lipids and hypertension, most loci identified by GWASs appear to act on the process of atherothrombosis independent of known or traditional risk factors.¹⁶⁵ This observation is of considerable importance because it suggests that novel pathways not yet exploited for vascular prevention are likely to play substantial roles in susceptibility to vascular events. Highly consistent findings for the 9p21 risk allele and at the PCSK9 locus provide an elegant example of emergence of a target from recent genetic findings leading rapidly to a novel therapy.

Second, the magnitude of risk associated with any one genetic variant tends to be small, yet specific patients such as those with early-onset disease often carry as many as 30 known variants, which together may contribute substantively to individual risk. The observation that most of the genetic variants associated with coronary disease localize in DNA sequences that do not code for a protein product has considerable relevance for future work.

Despite the strength of these emerging data, the use of individual SNPs or multimer genetic panels to predict incident cardiovascular events has proved disappointing. Even with clear replication in more than 20 independent cohorts, no study has shown that

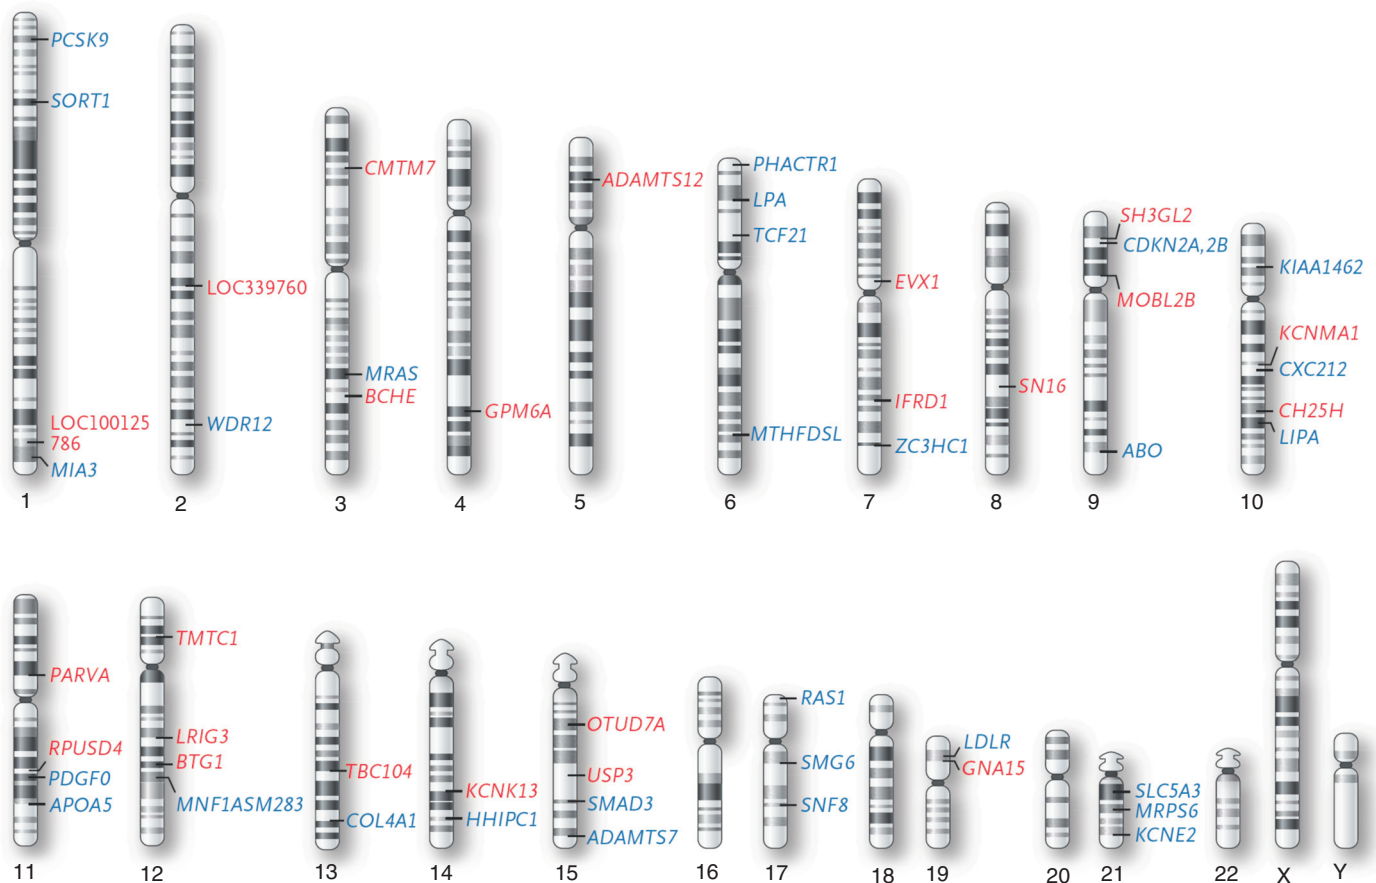

FIGURE 42-19 Genomic locations of genetic variants associated with myocardial infarction and heart failure. (From O'Donnell CG, Nabel EG: *Genomics of cardiovascular disease*. *N Engl J Med* 365:2098, 2011.)

FIGURE 42-21 Cumulative incidence of first cardiovascular events according to a 101-SNP validated genetic risk score (left), a 12-SNP validated genetic risk score (center), and by family history (right). (From Paynter NP, Chasman DI, Pare G, et al: Association between a literature-based genetic risk score and cardiovascular events in women. *JAMA* 303:631, 2010.)

measurement of 9p21 alters global risk prediction and in one major study, knowledge of 9p21 status led to, if anything, a worsening of risk prediction as compared with usual risk factors.¹⁶⁶ The use of multiple-marker approaches initially generated greater optimism but also has had limited clinical success. In the Malmo Diet and Cancer Study, a genotype score based on nine validated SNPs that are known to be associated with modulation of levels of LDL or HDL cholesterol was found to be an independent risk factor for incident cardiovascular disease¹⁶⁷ (Fig. 42-20). Yet, in that study, the genetic risk score did not improve discrimination and only modestly improved reclassification (see Fig. 42-20). An analysis of the Women's Genome Health Study also showed limited clinical efficacy. In this investigation, 101 previously validated SNPs from earlier GWASs informed the generation of a "second-generation" genetic risk score.¹⁶⁸ In this NIH-funded cohort of U.S. women, knowledge of this comprehensive and reproducible SNP panel only marginally improved risk prediction; the age-adjusted hazard attributable to the 101 SNP score was 1.02, and after adjustment for traditional risk factors, the per-allele hazard ratio was 1.00 (95% CI, 0.99 to 1.01). Nonetheless, in the same study, knowledge of parental history of early atherosclerosis remained an independent and important predictor of risk that improved net reclassification

(Fig. 42-21). The validated global risk prediction scores such as the Reynolds risk score, which include traditional risk markers as well as parental history of premature atherosclerosis, highlight the importance of family history as a variable that reflects both shared genetics and shared environment.

Interventions for Prevention Based on Genotype

Although the usefulness of genetic panels for risk prediction has proven modest, new knowledge of cardiovascular genetics not only is producing novel targets for therapy but also is introducing to clinical practice the potential for improved drug safety and efficacy. Broadly stated, *pharmacogenetics* is the study of inherited and acquired genetic variation in drug response that can affect both individuals and selected populations¹⁶⁹ (see also Chapters 7 and 9). Prominent examples of clinical applications in which knowledge of genotype has potential impact for cardiovascular medicine are in the prediction of statin-induced myopathy, in clopidogrel efficacy, and in warfarin dosing. With regard to statins, in a pharmacogenetic study conducted within the Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH), a common variant in *SLCO1B1* was identified that was strongly associated with an

increased risk of simvastatin induced myopathy.¹⁷⁰ This observation is of interest, because *SLCO1B1* encodes an organic anion-transporting protein known to regulate the hepatic uptake of statins. For the relevant SNP in this region, the hazard ratio for myopathy was 4.5 per copy of the C allele (and almost 17 in the CC as compared with TT homozygotes) (Fig. 42-22).

With regard to clopidogrel, investigators in the Thrombolysis and Myocardial Infarction (TIMI) group have found that genetic variation in the cytochrome P-450 system can alter antiplatelet function in a clinically meaningful manner. Specifically, among acute ischemia patients treated with clopidogrel, carriers of at least one cytochrome reduced-function allele had significantly lower levels of the active metabolite of clopidogrel, diminished platelet function, and an increase in vascular events as well as stent thrombosis.¹⁷¹

Finally, with regard to warfarin dosing, several genetic polymorphisms that interfere with hepatic metabolism and vitamin K epoxide reductase affect the dose of warfarin required to achieve a specific therapeutic target and on the speed with which an individual patient achieves that goal. To date, however, controversy persists regarding whether any of these pharmacogenetic effects should lead to clinical testing. Ongoing clinical trials should determine whether patient outcomes improve as a result of genetic knowledge.

Such limitations aside, routine preventive practice should include evaluation of family history. In the Framingham Offspring Study, when compared with those with no parental history of cardiovascular disease, men with at least one parent with premature atherothrombosis (onset younger than 55 years of age for fathers, and younger than 65 years of age for mothers) had an age-adjusted odds ratio of 2.6 (95% CI, 1.7 to 4.1), whereas the similar odds ratio for women was 2.3 (95% CI, 1.2 to 3.1).¹⁷² These effects compare in magnitude with those of smoking, hypertension, and hyperlipidemia in the Framingham cohort itself. The JUPITER trial affirmed the importance of family history as a clinical marker of risk. Within JUPITER, those subjects with a family history of atherosclerosis experienced a 62% reduction in first vascular events associated with statin therapy as compared with a 39% reduction among those without a family history. Thus trial evidence already exists suggesting that family history could be considered a “coronary heart disease risk equivalent” for purposes of statin prescription in primary prevention.

FIGURE 42-22 Estimated cumulative risk of myopathy for patients taking simvastatin according to polymorphism at the *SLCO1B1* gene. (From SEARCH Collaborative Group, Link E, Parish S, et al: *SLCO1B1* variants and statin-induced myopathy—a genomewide study. *N Engl J Med* 359:789, 2008.)

ENVIRONMENTAL EXPOSURES AND ASSOCIATED INTERVENTIONS

Depression, Mental Stress, and Cardiovascular Risk

Psychosocial factors such as depression, chronic stress and anxiety, chronic hostility and anger, social isolation, and perceived lack of social support have consistently been linked with the risk of coronary heart disease (see also Chapter 86). Depression is common in the United States, with the CDC estimating that 9.1% of U.S. adults—or 1 in 10—meet the criteria for current depression, including 4.1% who meet the criteria for major depression.^{173,174} An increased prevalence of depression has been reported for the southeastern United States, where a greater prevalence of chronic conditions associated with depression has been observed (e.g., obesity and stroke). By state, age-standardized estimates for current depression range from 4.8% in North Dakota to 15.0% in Puerto Rico.

Negative emotions, particularly depression, have consistently associated independently with the development of cardiovascular morbidity and mortality in patients without known cardiovascular disease, and patients with known coronary heart disease have higher prevalence of depression.^{175,176} Depression in otherwise healthy persons almost doubles the risk of developing coronary heart disease. In the INTERHEART case-control study including more than 15,000 postinfarction patients from 52 countries, psychosocial stress was associated with vascular risk in all regions of the world, in both sexes, and in all ethnic groups. The magnitude of effect of depression was similar to that of the major coronary risk factors.¹⁷⁷ Approximately 20% of patients hospitalized for acute coronary syndromes have major depressive disorder on admission or within a few weeks thereafter; among these patients, the mortality rate is approximately 2.5 times that in patients without depression after adjustment for infarct severity and cardiovascular risk factors, with risk increasing with severity of depression.¹⁷⁸ Major depression and elevated depressive symptoms are associated with worse prognosis in patients with coronary heart disease, with more severe depression correlated with earlier and more severe cardiac events. Depression appears to remain associated with at least a doubling in risk of cardiac events over 1 to 2 years after an MI.

Both physiologic and behavioral mechanisms have been postulated to explain the link between depression and coronary heart disease. These include effects on inflammation, endothelial dysfunction, increased platelet activity, increased whole blood serotonin, enhanced activity of the hypothalamic-pituitary-adrenal axis, alterations in cardiac autonomic tone, and elevated catecholamine levels, as well as worse underlying severity of disease; adverse lifestyle factors including poor diet, smoking, and lack of exercise; and non-adherence to medications and inability to change adverse lifestyle risk factors.^{175,178} (Fig. 42-23). For mental stress, the adrenergic stimulation can augment myocardial oxygen requirements and aggravate myocardial ischemia; and cause coronary vasoconstriction, particularly in atherosclerotic coronary arteries. Studies have further linked mental stress to platelet and endothelial dysfunction, the metabolic syndrome, and the induction of ventricular arrhythmias. The extent to which each of these proposed mechanisms, alone or in combination, explains the increased risk on cardiovascular events remains unknown. Although depression is associated with an increased prevalence of hypertension, smoking, and lack of physical activity, the effects of depression on overall risk remain after adjusting for these and other traditional risk factors. Analyses from the Nurses' Health Study of the individual and joint effects of depression and diabetes on all-cause and cardiovascular mortality indicated a significantly increased risk of these endpoints for depression alone as well as diabetes alone, after control for a large number of other demographic variables, lifestyle factors, and major comorbid conditions. Patients with both depression and diabetes showed the highest risk for cardiovascular death.¹⁷⁹ Such findings, as well as observations that depressed persons have increased platelet activation, elevated levels of hsCRP, and decreased heart rate variability, support depression as an independent predictor of cardiovascular events.

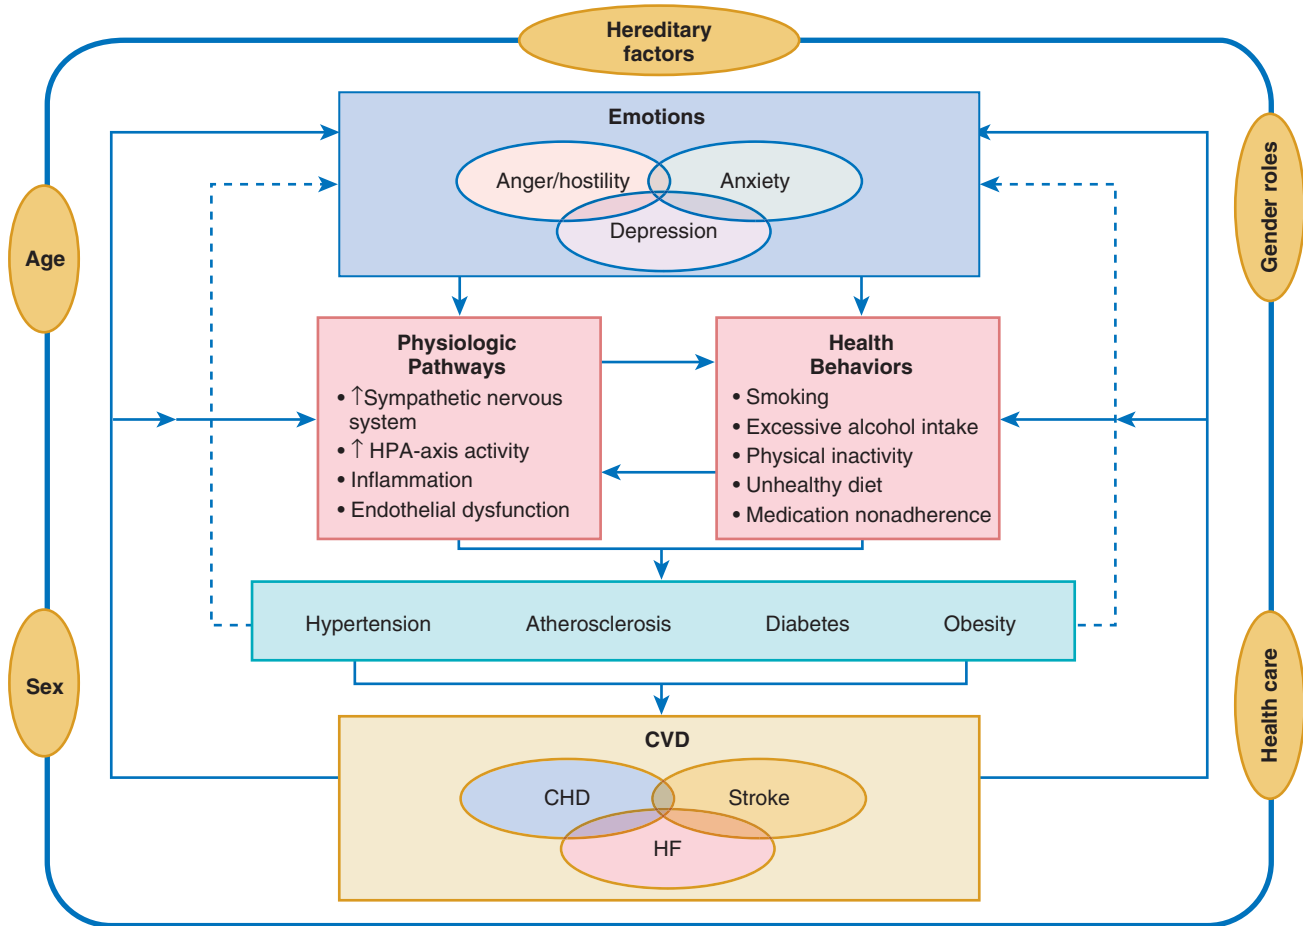

FIGURE 42-23 Conceptual framework linking emotions to cardiovascular disease (CVD). HF = heart failure; HPA = hypothalamic-pituitary-adrenal. (From Weidner G, Spaderna H: *Emotions and cardiovascular disease*. In Goldman MB, Troisi R, Rexrode KM [eds]: *Women and Health*. 2nd ed. San Diego, Academic Press, 2013, pp 991-1002.)

Chronic caregiving and work-related stress also have gained recognition as a source of vascular risk. Work stress has two components—job strain, which combines high work demands and low job control, and effort-reward imbalance, which more closely reflects economic factors in the workplace. Both components are associated with an approximate doubling of risk for MI and stroke. Other psychological metrics, including anger and hostility scales as well as negative social interactions, also are associated with elevated vascular risk.

In addition to the effects of these chronic stressors, a body of observational evidence has suggested a role for acute emotional triggers in precipitating an MI, including acute stress, occurrence of catastrophic events, excessive anger, anxiety, sadness, and grief.¹⁸⁰ Among patients with heart disease, those with posttraumatic stress disorder were more likely to report medication nonadherence, physical inactivity, and smoking, with the effect largely explained by comorbid depression.¹⁸¹ Lifetime exposure to traumatic psychological stress also increases risk for morbidity and death in patients with cardiovascular disease, possibly through an increase in chronic inflammation.¹⁸²

Interventions for Psychosocial Factors

Extensive data suggest a high prevalence of psychosocial risk factors such as depression and stress associated with the risk of incident coronary heart disease and subsequent events after MI (see also Chapter 86). Effective treatment options for depression include antidepressant drugs, cognitive behavioral therapy, and physical activity. To date, no randomized trial data have definitively demonstrated a reduction in risk of cardiovascular endpoints with interventions for depression such as pharmacologic measures. The Sertraline Antidepressant Heart Attack Randomized Trial (SADHART)

demonstrated the safety of this selective serotonin reuptake inhibitor (SSRI) for treatment of recurrent depression in 369 hospitalized patients for acute MI or unstable angina.¹⁸³ Those in the sertraline group had better scores on depression and mood scales, particularly those with premorbid depression. Yet, sertraline had no more impact than placebo on left ventricular ejection fraction, treatment-emergent ventricular premature complex runs, or other cardiac measures. Subsequently, the SADHART-CHF trial tested sertraline versus placebo in 500 men and women with chronic systolic heart failure and current major depressive disorder who underwent evaluation of quality of life and physiologic metrics at 12 weeks.¹⁸⁴ Sertraline showed safety in patients with significant heart failure, but did not provide greater reduction than placebo in depression or improved cardiovascular status. The ENRICHED (Enhancing Recovery in Coronary Heart Disease Patients) trial recruited 2481 patients (26% with perceived lower social support, 39% with clinical depression, and 34% with both) within 28 days of MI. Half were randomized to cognitive-behavioral therapy and drug therapy if needed, and half to usual medical care. The cognitive behavioral-drug intervention modestly improved depression and social isolation, but did not increase event-free survival.¹⁸⁵ The Heart and Soul Study was a prospective cohort study that observed 1017 outpatients with stable coronary heart disease for a mean period of 4.8 years to evaluate the mechanisms of association between psychological factors and cardiovascular results. A 50% increase in cardiovascular events was observed among patients with depressive symptoms, but health behaviors, especially physical inactivity, largely explained this association.¹⁸⁶ These findings raised the hypothesis that behavior modifications—and in particular, physical activity—could modify the increased risk of cardiovascular events associated with depression. The UPBEAT

(Understanding the Prognostic Benefits of Exercise and Antidepressant Therapy) study evaluated the efficacy of exercise and antidepressant medication in reducing depressive symptoms and improving cardiovascular biomarkers in depressed patients with coronary heart disease.¹⁸⁷ A total of 101 outpatients with coronary heart disease and elevated depressive symptoms underwent randomization to aerobic exercise, sertraline, or placebo. Both exercise and sertraline showed equal efficacy in significantly reducing depressive symptoms compared with placebo. Exercise and medication resulted in greater improvement of borderline significance in heart rate variability compared with placebo, and exercise resulted in a nonsignificant improvement in heart rate variability compared with sertraline. Both exercise and sertraline showed trends toward improvement of cardiovascular biomarkers.

Thus, at this time, adequately powered randomized trials have not established whether screening for depression coupled with SSRI treatment will improve survival and cardiovascular outcomes. A meta-analysis of in patients with depression and coronary heart disease concluded that when only considering properly randomized trials, SSRIs provided significantly greater improvement in depression symptoms, but no significant differences in mortality or coronary heart disease readmission rates compared with placebo. The trials discussed previously did not disclose significant cardiovascular adverse effects of SSRIs, even during acute coronary syndromes (with attendant instability clinically and in comedications). Other studies, however, have suggested adverse effects, such as an increased risk of hemorrhagic and fatal stroke in postmenopausal women without cardiovascular disease.¹⁸⁸ Despite these uncertainties, the most recent American Heart Association Science Advisory on depression and coronary heart disease¹⁸⁹ recommends that because of the high prevalence of depression among patients with coronary heart disease, all patients with coronary heart disease be screened for depression, and the European Guidelines on cardiovascular disease prevention in clinical practice suggest that a “prudent approach” would be to offer patients with clinically significant depression or anxiety treatment with psychotherapy and antidepressant/anxiolytic medication.⁴⁶ Cardiovascular practice often omits this aspect of patient care.

Physical Activity

A large body of epidemiologic evidence that has accumulated since the 1950s demonstrates that physical activity is associated with reduced rates of cardiovascular morbidity and mortality, as well as all-cause mortality (see also Chapters 47 and 79). A recent review showed this correlation to pertain across a wide age range, in both sexes, as well as among different race-ethnic groups.¹⁹⁰ Notable advances in recent years include elucidation of the dose-response relation (i.e., what percent risk reduction is associated with different levels of physical activity), as well as suggestive, but not yet definitive, research showing that sedentary behavior may constitute an independent risk factor, even among persons who engage in sufficient physical activity to meet the current guidelines, described subsequently. Unfortunately, 4 of 10 people in the United States do not meet guidelines, based on self-reported surveys, and a much higher proportion based on objective measurement of physical activity using accelerometers.¹⁹¹ This lack of activity applies worldwide, such that inactivity may cause as many deaths globally each year as those from smoking, because inactive persons outnumber smokers.¹⁹²

The federal government issued its first-ever physical activity guidelines in 2008, which ask adults to do at least 150 minutes per week of moderate-intensity physical activity (e.g., walking), or 75 minutes per week of vigorous activity (e.g., jogging), or a combination of activities of both intensities that expends an equivalent amount of energy.¹⁹³ Although the guidelines stipulate a total amount of physical activity, spacing of episodes throughout the week may minimize the risk of musculoskeletal injuries; the guidelines also require activities to occur for periods of at least 10 minutes' duration. For those persons who do not meet the recommended minimum, the guidelines encouragingly state that “some physical activity is better than none.” A 2011

FIGURE 42-24 Meta-analysis showing dose-response relation between physical activity and risk of coronary heart disease. The thick blue line represents a fitted curve and the thin blue lines the confidence intervals. (From Sattelmair J, Pertman J, Ding EL, et al: Dose response between physical activity and risk of coronary heart disease: A meta-analysis. *Circulation* 124:789, 2011.)

meta-analysis quantified the precise dose-response relation for the first time (Fig. 42-24), showing that persons meeting the recommended minimum had a 14% lower risk of coronary heart disease, compared with those engaging in no leisure time activity.¹⁹⁴ At twice the minimum guideline level, a 20% risk reduction was seen. Risks continued to decline at higher levels of energy expenditure, albeit with more modest magnitudes of additional risk reduction. Even achievement of half of the guideline-recommended amount of physical activity yielded a significant risk reduction.

These findings, related to the primary prevention of cardiovascular disease, all have come from observational epidemiologic studies. Although such study designs cannot prove causality, the totality of evidence strongly indicates a causal relation. In particular, many plausible biologic mechanisms support this inverse relation described in more detail further on, as demonstrated in experimental settings (i.e., randomized controlled trials). Furthermore, in secondary prevention, randomized controlled trials of cardiac rehabilitation that include an exercise component have shown reductions in all-cause and cardiovascular mortality, compared with usual care, over a follow-up period of at least 12 months.¹⁹⁵

Several plausible biologic mechanisms can explain the cardioprotective effect of physical activity.¹⁹³ Regular physical activity has been shown to reduce myocardial oxygen demand and increase exercise capacity (i.e., improving cardiorespiratory fitness), which correlate with lower levels of coronary risk. Physical activity also lowers systolic and diastolic blood pressure; improves insulin sensitivity and glycemic control, with major benefits for diabetic patients, including reductions in glycated hemoglobin along with reduced requirements for therapy; and improves dyslipidemia, as well as vascular inflammation. Regular physical activity is associated with lower CRP levels (particularly when adiposity decreases) and hemostatic variables including tissue-type plasminogen activator, fibrinogen, von Willebrand factor, fibrin D-dimer, and plasma viscosity. It also enhances endogenous fibrinolysis and coronary endothelial function. Physical activity helps control body weight, and lower levels of adiposity improve many of the aforementioned physiologic parameters, which are cardiovascular risk factors.

For people who consume a usual American diet, the level of physical activity recommended by the federal guidelines may not be sufficient to prevent the weight gain that occurs with age. Nonetheless, the available data clearly indicate that physical activity lowers cardiovascular risk among not only individuals with normal body mass index but also those who are overweight or obese. Because of the difficulty in maintaining sustained weight loss among overweight and obese persons, the importance of physical activity—even without weight loss—for cardioprotection should be emphasized to patients. A recent analysis pooling data from

several studies¹⁹⁶ demonstrated that persons of normal weight who met physical activity guidelines lived 4.7 years longer than normal-weight persons with no leisure time physical activity. Among overweight persons, the corresponding years of life gained were 3.9; even class I and class II or more obese persons gained 3.4 and 2.7 years, respectively.

Recently, interest has burgeoned in understanding the role of sedentary behaviors on health, independent of physical activity level, because one can be both sedentary and physically active (e.g., an office worker who sits during most of the workday but who also jogs regularly). This relation is biologically plausible: Animal and human studies show that sedentary behavior is associated with elevated levels of cardiometabolic biomarkers and a poor cardiovascular risk factor profile. A recent meta-analysis of prospective cohort studies¹⁹⁷ estimated that if every adult in the United States decreased sitting time to less than 3 hours per day, life expectancy of the population would increase by 2.0 years, and if every adult reduced television viewing time to less than 2 hours per day, life expectancy would increase by 1.4 years.

Finally, physical activity can be associated with adverse events (see also Chapter 79).¹⁹³ The most common adverse events are musculoskeletal injuries, and risks relate directly to the amount and intensity of physical activity undertaken. At the level recommended by the federal guidelines, risk is low. One of the most severe adverse events related to physical activity is the risk of a sudden cardiac event (e.g., sudden death) during or shortly after exercise, but these events are extremely rare. *Vigorous intensity* activities can precipitate such events, particularly when unaccustomed. Adding a small amount of light to moderate intensity activity (e.g., walking, 5 to 15 minutes per session, two or three times a week) carries no known risk for sudden severe cardiac events, compared with periods of less intense activity or at rest. Compared with inactive people, active people are at lower overall risk for cardiovascular disease, because when averaged over the whole day, the risk during activity and during all other periods in active people yields a lower average risk than in inactive people. The benefits of regular physical activity clearly outweigh the inherent risk of adverse events.

Interventions to Increase Physical Activity

How can clinicians help patients increase their physical activity levels? A recent meta-analysis examined the effectiveness of physical activity promotion in the primary care setting, based on randomized controlled trials with at least 12 months of follow-up.¹⁹⁸ A wide range of interventions were reported, with most including the use of written materials and two or more sessions of physical activity counseling, delivered face to face or by telephone. A range of professionals—including primary care physicians, nurses, physiotherapists, exercise or physical activity specialists, health educators, health promotion specialists, or trained facilitators from a range of health professions—delivered the interventions. The interventions resulted in significant small to medium-sized effects, with the estimated “number needed to treat” for one additional sedentary adult to achieve recommended levels of physical activity at 12 months was 12, which compared favorably with the number of 50 to 120 estimated for smoking cessation. Another systematic review reported that provision of pedometers to participants in physical activity promotion programs, increased step counts significantly by some 2000 to 2500 steps/day (approximately 1 mile).¹⁹⁹

Individual approaches toward increasing physical activity levels, although important, have limited impact, because they focus only on a single patient. A comprehensive public health approach would involve health agencies; schools; businesses; policy, advocacy, nutrition, recreation, planning, and transport agencies; and health care organizations. A recent review identified several evidence-based interventions found to increase physical activity levels in populations.²⁰⁰ These included community-wide campaigns, mass media campaigns, and decision prompts encouraging the use of stairs versus lifts and escalators; initiatives to increase social support for physical activity within communities, specific neighborhoods, and worksites; school-based strategies for children and adolescents,

which include physical education, classroom activities, afterschool sports, and active transport; and environmental and policy approaches (e.g., active transport policies) to create or enhance access to places for physical activity.

Obesity and Weight Loss

Rates of obesity have risen to epidemic proportions in the United States and worldwide, with prevalence of obesity generally higher in women than in men. Americans have never been heavier and have the highest body-mass index (BMI) of any high-income country. Data from the NHANES show the pattern of increased prevalence of obesity over the last 50 years in the United States. The population prevalence of *obesity*, defined as a BMI of 30 or higher, showed little change between 1960 and 1980, followed by an increase of almost 8 percentage points between the 1976-to-1984 and 1988-to-1994 surveys, and then a similar increase between the 1988-to-1994 and 1999-to-2000 surveys. Over the period 1999 to 2008, smaller changes occurred in the prevalence among men than seen previously, and no significant change occurred in the prevalence in women. Data from the latest NHANES survey of 2009 to 2010 indicate an age-adjusted prevalence of obesity in the United States of 35.5% among adult men and 35.8% among adult women, with no significant change compared with 2003 to 2008 for men or women.²⁰¹ The age-adjusted prevalence of overweight and obesity combined (BMI \geq 25) is 68.8% overall—73.9% among men and 63.7% among women (Fig. 42-25).

The prevalence of obesity differs substantially by race and ethnic group. In the period 2009 to 2010, the prevalence of obesity in men ranged from 36.2% among non-Hispanic white men to 38.8% among non-Hispanic black men. For women, the range is from 32.2% among non-Hispanic white women to 58.5% among non-Hispanic black women. The overall prevalence of obesity does not differ significantly between men and women. The age-adjusted values for BMI of 35 or greater (grade 2 and grade 3 obesity) range from 11.4% among Mexican American men to 20.0% for non-Hispanic black men; and for women, from 16.6% for non-Hispanic white women to 30.7% for non-Hispanic black women. For grade 3 obesity (BMI \geq 40), non-Hispanic black women have the highest prevalence (17.8%).

Over the period from 1999 through 2010, obesity did not increase significantly among women overall, but rose significantly for non-Hispanic black women and Mexican American women. The prevalence of obesity in men showed a significant linear trend for increase over the 12-year period. Although the prevalence of BMI-defined obesity in adults in the United States continues to exceed 30% in most sex-plus-age groups, these data suggest attenuation in the rate of increases in the population prevalence of obesity previously observed. On the other hand, there was no indication of decline in the prevalence of obesity in any group. Although it is difficult to make international comparisons, the prevalence of obesity appears to be higher in the United States than in other high-income countries such as Canada or England, and the trends seen in a number of other countries also suggest a similar pattern of possible leveling of the prevalence of obesity.

Childhood obesity has caused increasing concern in the United States. The prevalence of childhood obesity increased in the 1980s and 1990s. In 2009 to 2010, 16.9% of U.S. children and adolescents from 2 through 19 years of age were obese, defined as the 95th percentile or higher on the BMI-for-age growth charts, 31.8% were either overweight (greater than or equal to the 85th percentile) or obese, and 12.3% exceeded the 97th percentile of BMI for age.²⁰² Overall, the prevalence of obesity among male children and adolescents (18.6%) was significantly higher than among females (15%). This pattern held for non-Hispanic whites, but no significant differences by sex were noted among Hispanic or non-Hispanic black children and adolescents.

The prevalence of obesity in children and adolescents differs significantly by race and ethnicity. Non-Hispanic black and Hispanic children and adolescents have a higher prevalence of obesity than non-Hispanic white youth. A total of 21.2% of Hispanic children and adolescents and 24.3% of non-Hispanic black children and

FIGURE 42-25 Overweight and obesity among U.S. adults 20 years of age and older, by sex: 1988 to 1994, 1999 to 2002, and 2007 to 2010. (From Goldman MB, Troisi R, Rexrode KM: *Women's health in the 21st century*. In Goldman MB, Troisi R, Rexrode KM [eds]: *Women and Health*. 2nd ed. San Diego, Academic Press, 2013, pp 5-20.)

adolescents were obese, compared with 14.0% of non-Hispanic white children and adolescents. Trend analyses over a 12-year period indicate a significant trend in obesity prevalence between 1999 to 2000 and 2009 to 2010 for male children and adolescents aged 2 through 19 years, but not in females. Although international comparisons are hindered by different measures of obesity in children and adolescents used throughout the world, estimates suggest that obesity tends to be higher in children and adolescents in the United States than in other high-income countries. Childhood obesity continues to increase in some countries, whereas in other countries or some U.S. subgroups it appears to have leveled. Although efforts both at the national level and at state and local levels focus on reducing childhood obesity, these results indicate that the prevalence of childhood obesity in the United States has not declined between 2003 and 2008 and between 2009 and 2010, and increases in obesity prevalence may have occurred among males. As with adults, however, the rapid increases in prevalence of obesity seen in the 1980s and 1990s have not continued in this decade.

Overweight and obesity are associated with increased all-cause mortality in a pooled analysis of 1.46 million white adults.²⁰³ Black women have a similar pattern of increased risk of death from any cause with increases in BMI of 25.0 or higher.²⁰⁴ Obesity strongly predicts incident cardiovascular disease and coronary heart disease, as well as type 2 diabetes mellitus and other chronic conditions, with risk increasing as BMI levels rise. Obese children have a risk for short-term health consequences, including the dramatic increases in type 2 diabetes among children and adolescents. They also have risk for long-term tracking of obesity to adulthood. Overweight or obese children who are obese as adults have increased risks of type 2 diabetes, hypertension, dyslipidemia, and carotid-artery atherosclerosis.⁸⁸ Yet non-obese adults who were overweight or obese during childhood have risks of these outcomes similar to those who were never obese. An elevated BMI in adolescence constitutes a substantial risk factor for obesity-related disorders in midlife.⁸⁹ Although the risk of diabetes associates mainly with increased BMI close to the time of diagnosis, the risk of coronary heart disease links to an elevated BMI both in adolescence and in adulthood.

Some question whether obesity itself is a true risk factor for cardiovascular disease over and above its impact on vascular risk mediated solely through interrelations with glucose intolerance, insulin resistance, hypertension, physical inactivity, and dyslipidemia. Midlife obesity, however, strongly presages hospitalization and future complications of coronary heart disease, even among those with few or no other major risk factors. In terms of the relative importance of obesity and physical activity as predictors of coronary heart disease risk, both fitness and fatness have implications for vascular risk. Obesity alone is associated with all-cause mortality regardless of level of physical activity.²⁰³ The distribution of body fat also is a factor in the development of coronary heart disease, with abdominal obesity posing a substantially greater risk in both men and women. The waist-to-hip ratio, a surrogate for centripetal or abdominal obesity, independently predicts vascular risk in women and in older men. The prevalence of abdominal obesity increases with age and varies by race and ethnicity. The mechanisms that link these anthropometric measures and coronary heart disease risk, particularly among disproportionately affected racial and ethnic minority groups, require further research.

The ideal approach to weight reduction lacks consensus. Effective treatment strategies generally involve a multifaceted approach, including dietary counseling, behavioral modification, increased physical activity, and psychosocial support. Observational studies and clinical trials suggest that pharmacotherapy and bariatric surgery hold promise in promoting weight loss. Prospective follow-up studies have shown that compared with usual care, obese patients receiving bariatric surgery had a reduced number of cardiovascular deaths compared with usual care.²⁰⁵ Yet, because bariatric surgery dramatically reduces diabetes shortly after surgery, before any substantial weight loss, observational studies of such patients may not mimic effect of diet-induced weight loss. Moreover, long-term success, long-term risks, and cost-effectiveness of bariatric surgery require fuller evaluation. Pharmacologic blockers of endocannabinoids promote weight loss and improve metabolic profiles, but concern about depression has forestalled their clinical use.

Specific dietary and lifestyle factors are associated independently with long-term weight gain, with a substantial aggregate effect and

implications for strategies to prevent obesity (see also Chapter 46). A prospective evaluation followed three separate cohorts that included more than 120,000 U.S. men and women who were free of chronic diseases and not obese at baseline, from 1986 to 2006, 1991 to 2003, and 1986 to 2006. The relationships between changes in lifestyle factors and weight change were evaluated at 4-year intervals, with multivariable adjustments made for age, baseline BMI, and lifestyle factors.²⁰⁶ Within each 4-year period, participants gained an average of 3.35 pounds, and weight change during follow-up was related strongly to the intake of a number of specific foods and lifestyle factors. Increased weight change over the 4-year period was associated with increased daily servings of potato chips, potatoes, processed meats, unprocessed red meats, butter, sweets and desserts, refined grains, sugar-sweetened beverages, and 100% fruit juice. Inverse weight changes were associated with increased daily servings of vegetables, nuts, whole grains, fruits, yogurt, low-fat or skim milk, whole milk, and zero-calorie soda. Such findings have supported the conduct of trials evaluating the effects on body weight of changes in consumption of specific foods or nutrients. Reduced consumption of sugar-sweetened beverages has been associated with reduction in weight gain and fat accumulation in normal-weight children, and in smaller increases in BMI in overweight and obese adolescents at 1 but not 2 years.^{207,208} Other studies have evaluated the interaction between a genetic predisposition to obesity and the intake of sugar-sweetened beverages. The genetic association with adiposity (measured on the basis of 32 BMI-associated loci) appeared to be more pronounced with greater intake of sugar-sweetened beverages.²⁰⁹

Intervention Studies of Weight Loss

Data from numerous observational studies and small or short-term randomized clinical trials have supported the substantial health benefits of weight loss. Modest weight loss of 5% to 10% is associated with a significant improvement in blood pressure among persons with and without hypertension. Modest weight loss improves the lipoprotein profile, yielding lower levels of serum triglycerides, higher levels of HDL cholesterol, and small reductions in total cholesterol and LDL cholesterol, as well as improvements in glucose tolerance and insulin resistance.

Yet no longer-term behavioral-nutrition weight loss trials (including the recent Look AHEAD study)⁹⁵ have reported a reduction in total mortality, cardiovascular disease or coronary heart disease, primarily because of the subjects' inability to maintain long-term weight loss in these trials. Despite promising data from cohort studies, randomized trials of weight loss interventions have provided mixed results. In a comparison of four popular diet regimens, as well as in a study of carbohydrate substitution, all interventions yielded modest weight reductions and beneficial effects, but with limited long-term adherence levels.²¹⁰ In one of the few trials to attempt follow-up evaluation beyond 1 year, reduced caloric intake resulted in clinically meaningful weight loss regardless of which macronutrients were emphasized, suggesting that caloric intake is more important than any specific dietary plan.²¹¹

A review of published trials evaluating the effectiveness of treatments for obesity in adults relevant to primary care indicates that behaviorally based approach resulted in a 6.6-pound greater weight loss in subjects in the intervention group than in control participants after 12 to 18 months, with more treatment sessions associated with greater loss, and with limited data suggesting weight loss maintenance for 1 year or longer.²¹² A number of individual trials have examined the importance of counseling, behavioral factors, and motivation in conjunction with lifestyle modification including diet and exercise.²¹³⁻²¹⁵ In a trial of weight loss during a 2-year period in response to three lifestyle interventions, all delivered by primary care providers in collaboration with auxiliary health professionals (lifestyle coaches) in their practices,²¹⁶ enhanced weight loss counseling helped approximately one third of obese patients achieve long-term, clinically meaningful weight loss (Fig. 42-26). Nonetheless, even trials limited to motivated participants have shown only modest weight reduction and maintenance in the long term.

In the past decade, researchers have come to recognize that the rising prevalence of obesity requires solutions beyond a biological

FIGURE 42-26 Estimated percent reduction in baseline weight over a 24-month period in the intention-to-treat population. (From Wadden TA, Volger S, Sarwer DB, et al: A two-year randomized trial of obesity treatment in primary care practice. *N Engl J Med* 365:1969, 2011.)

approach alone, and examined how the built environment can influence physical activity and diet. Similarly, because a substantial burden of obesity and poor dietary intake exist among the poor and less well educated, community-based efforts such as the “total community approach” being implemented in many European towns is being evaluated as an alternative model for social intervention. A sustained worldwide effort is needed to monitor, prevent, and control obesity, with many parties, including governments, international organizations, the private sector, and civil society, needed to contribute complementary actions in a coordinated approach.²¹⁷ In the meantime, all preventive cardiology practices should encourage individual weight control, given obesity’s strong association with cardiovascular disease and its ability to be measured by a practical and easily obtainable measurement of BMI.

Diet, Moderate Alcohol Consumption, and Dietary Supplements

Diet

A large body of evidence, both from epidemiologic and intervention studies, has demonstrated that dietary factors have an important impact on coronary heart disease risk (see also Chapter 46). Worldwide, striking differences in dietary habits and rates of chronic diseases exist. Cross-cultural studies have long supported the role of diet in coronary heart disease as well as in other chronic diseases. Dietary habits also influence multiple cardiovascular risk factors, including both established risk factors (blood pressure, lipoprotein profiles, glucose levels, and obesity), as well as novel risk factors (such as inflammation).

A solid body of evidence has demonstrated that in addition to the identification of individual foods and nutrients that can improve health and prevent cardiovascular disease, several heart healthy dietary patterns have been identified to assess more global dietary quality.²⁹ Patterns such as the Healthy Eating Index, Alternative Healthy Eating Index, western versus prudent dietary patterns, Mediterranean dietary pattern, and the DASH-type diet are consistent in emphasizing fruits, vegetables, other plant foods such as beans and nuts, and in many patterns, whole grains and fish; with limited or occasional dairy products; and limiting red meats or processed meats and fewer refined carbohydrates and other processed foods. These dietary patterns conform with the food-based priorities for cardiovascular health that include foods that are higher in dietary fiber, healthy fatty acids, vitamins, antioxidants, potassium, other minerals, and phytochemicals, and lower in refined carbohydrates, sugars, salt, saturated fatty acids, dietary cholesterol, and trans fat.

effects of selected foods, nutrients, and dietary patterns on cardiovascular diseases.²¹⁸ Clear evidence from randomized trials demonstrates significant improvement in multiple cardiovascular risk factors associated with these dietary patterns (Fig. 42-27). These overall changes in risk factors are of a magnitude that would predict

substantial reductions in risk of cardiovascular disease. Women who reported adhering to the DASH-type diet demonstrated reductions in systolic blood pressure by 7.1 mm Hg in those without hypertension and by 11.5 mm Hg in those with hypertension. Women who adhered to either a DASH-type diet or an alternate Mediterranean Diet Index

had a lower risk of incident coronary heart disease and stroke after 20 years of follow-up.^{219,220} Most recently, in a 5-year randomized trial conducted in Spain, a Mediterranean diet supplemented with either extra virgin olive oil or mixed nuts was associated with a 30% reduction in vascular event rates,²²¹ with high levels of compliance (Fig. 42-28).

A number of evidence-based recommendations have been published in the last three years, summarizing the foods, nutrients, and dietary patterns for reduction of cardiovascular disease.^{29,40,221} Table 42-4 summarizes the current AHA Diet and Lifestyle Recommendations for cardiovascular disease risk reduction using NHANES data from 2005 to 2006 for women 20 years of age or older.²⁹ Table 42-4 also provides the percentages of women by race and ethnicity meeting these dietary guidelines. There is substantial room for improvement in meeting the AHA dietary recommendations for reducing cardiovascular risk. Between 1999 and 2004, only 19.4% of hypertensive adults were following a DASH-type diet, down from 26.7% between 1988 and 1994. Moreover, among older U.S. adults (60 years of age and older) in 1999 to 2002, although 72% met guidelines for dietary cholesterol intake, only between 18% and 32% met guidelines for the Healthy Eating Index food groups (meats, dairy, fruits, vegetables, and grains). In fact, between 1994 and 2005, the average consumption of fruits and vegetables declined slightly. On the basis

of the Healthy Eating Index score, only 17% of older U.S. adults consumed a good-quality diet.

The AHA strategic impact goals through 2020 recommend the following specific dietary goals²²²

In the context of a diet that is appropriate in energy balance, pursuing an overall dietary pattern that is consistent with a DASH (Dietary Approaches to Stop Hypertension)-type eating plan, including but not limited to:

- Fruits and vegetables: 4.5 cups or more per day
- Fish: 3.5 oz servings or more per week (preferably oily fish)
- Fiber-rich whole grains (1.1 g of fiber or more per 10 g of carbohydrate: three or more 1 oz—equivalent servings per day)
- Sodium: below 1500 mg per day
- Sugar-sweetened beverages: 450 kcal (36 oz) or less per week.²²²

Although behavior-based strategies can improve an individual patient's diet quality, a substantial and sustained population impact ideally involves public health strategies at community, state, and national levels. A wide range of evidence-based, population-based strategies to promote effectively lifestyle changes to improve dietary habits, as well as to increase physical activity and reduce smoking, are recognized. These interventions can be categorized into six

broad domains: media and educational campaigns; labeling and consumer information; taxation, subsidies, and other economic incentives; school and workplace approaches; local environmental changes; and direct restriction and mandates.²²³ This framework can inform potential strategies to improve diet and develop partnerships to translate into action the evidence reviewed previously.

Moderate Alcohol Consumption

Alcohol consumption has complex effects on cardiovascular disease, and can be associated with either beneficial or adverse cardiovascular outcomes. Habitual *heavy* alcohol consumption increases total mortality, cardiovascular disease mortality, coronary heart disease, and stroke. By contrast, a consistent body of observational epidemiologic evidence has shown that light to moderate alcohol consumption, compared with nondrinkers, associates inversely with risk of heart attack, ischemic stroke, peripheral vascular disease, sudden cardiac death, diabetes

mellitus, and death from all cardiovascular causes. Data for both men and women regarding risk of mortality from cardiovascular endpoints such as coronary heart disease, stroke, and sudden cardiac death illustrate a U-shaped relationship of reduced risk with moderate alcohol consumption²²⁴ (Fig. 42-29). Moderate alcohol consumption is associated with decreased cardiovascular risk for both primary and secondary prevention, in both men and women. Defined as up to one drink per day for women⁴⁰ and up to two drinks per day for men, moderate alcohol consumption consistently corresponds to a reduction in risk of cardiovascular disease of approximately 20% to 40%.

Demonstrated physiologic effects from basic research and randomized trials underlying the observed benefits of moderate alcohol consumption on risk of cardiovascular disease include raising of HDL cholesterol, improvements in fibrinolytic capacity and insulin resistance, and reductions in platelet aggregation and systemic inflammation. Although some investigators suggest that red wine may have particular cardioprotective properties because of its nonalcohol component of resveratrol and other components, evidence from

trials of risk factors as well as prospective cohort studies of clinical end points have found equal benefits for all forms of alcohol when consumed in moderation, supporting that alcohol per se accounts for most of the observed protective association with alcoholic beverage consumption.

Any individual or public health recommendation must consider the complexity of alcohol's metabolic, physiologic, and psychological effects.²¹⁸ The 2010 Dietary Guidelines for Americans recommend that if alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age. With alcohol, the difference between daily intake of small to moderate quantities and large quantities may tip the balance between preventing and causing disease. Because of the health hazards of alcohol associated with higher intake, moderate alcohol use does not offer a desirable population-based strategy to reduce cardiovascular risk. Discussions of alcohol consumption require individual considerations and should take into account other medical problems, other coronary risk factors, comorbid conditions, and family history of medical conditions or alcoholism. Patients who are heavy drinkers merit a recommendation to limit intake. Guidelines discourage the initiation of moderate alcohol

drinking to reduce risk of heart disease. People who already drink alcohol on a moderate basis can receive the information that this pattern of alcohol consumption is associated with a decreased risk of cardiovascular disease.

Dietary Supplements

Dietary supplement use is common in the United States, among adult men and women and children. More than half (53%) of U.S. adults in the period 2003 to 2006 used dietary supplements, most commonly multivitamins and minerals.²⁹ Observational studies have consistently reported lower rates of coronary heart disease events among those who take dietary supplements. Yet large-scale randomized trials of most dietary supplements have generally shown no significant benefits for cardiovascular risk, and even have raised potential for harm. Currently available evidence suggests provides greater justification for a focus on evidence-based foods and overall dietary patterns than on individual nutrients or supplements for primary prevention of cardiovascular disease.

The evaluation of the role of vitamin E supplementation in the prevention of cardiovascular disease has underscored the importance of randomized trials in the evaluation of potentially

heart-healthy foods and nutrients. Basic research had suggested that oxidative stress contributes to the development of atherosclerotic disease, and that vitamin E may delay or prevent various steps in atherosclerosis. Observational data had strongly suggested that high doses of vitamin E reduced the risk of coronary heart disease, particularly with regard to secondary prevention. Completed secondary prevention trials, however, demonstrated that vitamin E had little if any impact on coronary heart disease risk, and two large-scale primary prevention trials of long duration of treatment and follow-up evaluation in women and men supported this lack of benefit.^{225,226} Similarly, plasma homocysteine levels consistently are associated with increased vascular risk in multiple prospective cohort studies, suggesting that homocysteine reduction with folate would reduce vascular event rates, but multiple trials of folate supplementation in patients with established vascular disease have shown no evidence of clinical benefit. At this time, no evidence-based recommendations support use of antioxidant supplements for the primary prevention of cardiovascular disease.

The use of multivitamin and mineral supplements has grown rapidly over the past several decades. Vitamin deficiency syndromes are uncommon in Western societies, although most people do not consume an optimal amount of all vitamins by diet alone, especially in the older adult population. In general, people who practice healthier lifestyles use multivitamins and minerals, thereby confounding the interpretation of the observational studies of the relationship between multivitamin/mineral use and chronic diseases. Fortification of foods also has raised safety concerns about exceeding upper limits. An NIH State-of-the-Science Conference Statement in 2006 reported on the safety and efficacy of multivitamin/mineral supplements and chronic disease prevention.²²⁷ The reporting investigators found few rigorous studies on which to base clear conclusions and recommendations and concluded that most of the studies they examined did not provide strong evidence for beneficial health-related effects of supplements taken singly, in pairs, or in combinations. They concluded that the present evidence was insufficient to recommend either for or against the use of multivitamin or mineral supplements by the U.S. public to prevent chronic disease. In 2012, the multivitamin component of the Physicians' Health Study, a large-scale, long-term randomized trial evaluating a common daily multivitamin versus placebo (as well as individual supplements of vitamin E, vitamin C, and beta-carotene versus placebo), reported lack of significant effects of a daily multivitamin on the combined endpoint of major cardiovascular events (nonfatal MI, nonfatal stroke, and cardiovascular mortality), or on the individual endpoints of total MI, total stroke, cardiovascular mortality, or total mortality, after a median follow-up period of 11.2 years.²²⁸ By contrast, randomized treatment with the multivitamin was associated with a modest (8%) but statistically significant reduction in risk of total cancer.²²⁹

The purported health benefits of vitamin D and marine omega-3 fatty acids have received increasing attention in both the medical literature and the popular press. Many clinicians now include vitamin D blood tests as part of routine laboratory work and recommend vitamin D supplements to patients without definitive randomized trial data supporting efficacy. Data from laboratory studies, ecologic studies, epidemiology investigations, and secondary analyses of small randomized trials have suggested a protective effect for vitamin D against a number of chronic diseases, including cardiovascular disease. Possible mechanisms of protection against cardiovascular disease include inhibition of inflammation, inhibition of vascular smooth muscle proliferation and vascular calcification, regulation of blood pressure and volume homeostasis, and regulation of glucose metabolism.²³⁰ In 2011, the Institute of Medicine critically reviewed the dietary requirements for calcium and vitamin D from almost 1000 studies of vitamin D in relation to a wide variety of health outcomes. The Institute investigators concluded that unlike the available scientific evidence supporting a key role of calcium and vitamin D in skeletal health, the evidence that vitamin D or calcium affects risk of nonskeletal chronic disease outcomes such as cardiovascular disease and cancer, is inconsistent and inconclusive and does not meet criteria for establishing a cause and effect relationship.²³⁰

Randomized trial data of vitamin D and cardiovascular disease are sparse, and few trials assessed cardiovascular disease or other chronic outcomes as primary prespecified endpoints. Moreover, emerging evidence suggests a curvilinear or U-shaped curve for several outcomes related to vitamin D, including cardiovascular disease, with the lowest risks at moderate levels and increased risk at both low and high levels. The Institute of Medicine report called for randomized trials to determine whether high-dose vitamin D supplements can lower the risk for nonskeletal illnesses and whether they pose any health risks.

Similarly, sales of fish oil supplements are rising, and an increasing number of foods are omega-3–fortified. The marine omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), components of fish and fish oil supplements, have shown considerable promise for the prevention of cardiovascular disease in laboratory and observational studies, as well as large randomized trials in secondary prevention or high-risk settings. These polyunsaturated fatty acids may have a number of mechanisms for cardioprotection including hypotriglyceridemic effects, hypotensive effects, decrease in platelet aggregation, and reduced susceptibility of the heart to ventricular arrhythmias.²³¹ Yet a meta-analysis of placebo-controlled trials showed a modest benefit only for cardiovascular mortality.²³² The recent AHA guidelines for the prevention of cardiovascular disease in women recommend the consideration of consumption of omega-3 fatty acids in the form of fish or in capsule form (e.g., EPA 1800 mg/day) in women with hypercholesterolemia and/or hypertriglyceridemia for primary and secondary prevention (with pregnant women being counseled to avoid eating fish with the potential for the highest level of mercury contamination).⁴⁰ No trials have studied marine omega-3 fatty acids supplements for the primary prevention of cardiovascular disease in a general population, however. Whether alpha-linolenic acid, the short-chain omega-3 fatty acid found in walnuts and other plant sources, provides the same potential cardiovascular benefit attributed to the EPA and DHA found in fish requires more research.

At this time, the available trial data do not support the recommendation of vitamin D or fish oil supplementation for the primary prevention of cardiovascular disease. Trials to evaluate definitively the roles of vitamin D and fish oil in the prevention of cardiovascular disease are addressing this gap. These trials include the VITamin D and Omega-3 TRIal (VITAL), an NIH-funded, large-scale randomized trial of vitamin D (cholecalciferol, 2000 IU/day) and a marine omega-3 fatty acid supplement (in the form of a fish oil supplement, EPA plus DHA, 1 g/day) for the primary prevention of cardiovascular disease and cancer. This currently ongoing trial enrolled more than 20,000 participants (women older than 55 years of age and men older than 50 years of age, with an oversampling of African Americans) with no known cardiovascular disease at baseline.²³³

Menopause and Postmenopausal Hormone Therapy

Age-specific coronary heart disease death rates in women lag approximately 10 years behind those of men. Rates of coronary heart disease mortality among women rise exponentially with age and vary substantially by race and ethnicity. Cardiovascular disease afflicts relatively few women younger than 45 years of age in developed countries, but by 60 years of age, it is the leading cause of death among women, both in the United States and worldwide (see also Chapter 77). More than 80% of cardiovascular disease deaths in women now occur in low-income and middle-income countries as a result of increasing longevity and large population sizes. Although men exhibit a higher incidence of coronary heart disease at every age as well as higher coronary heart disease mortality rates, the gap narrows substantially as women's rates increase after either natural menopause or bilateral oophorectomy.^{29,30}

A wide range of factors may explain the increased risk of coronary heart disease after menopause. These include adverse changes in lipid and glucose metabolism that result in an increase in LDL cholesterol and a decrease in HDL cholesterol, an increase in glucose

intolerance, and changes in hemostatic factors and vascular function. These changes appear to result not only from the decline in endogenous estrogen that accompanies menopause but from the hormonal shift toward androgen dominance as estradiol levels fall.

The observed increase in coronary heart disease in women after menopause, the numerous observational studies that consistently demonstrated that ever and current use of postmenopausal hormone therapy was associated with a reduced risk of coronary heart disease, the observed favorable effects of oral estrogen on the lipid profile in basic research and small clinical trials, and in response to recommendations from groups such as the American College of Physicians, all led to the widespread use in the 1990s of hormone therapy in postmenopausal women to prevent cardiovascular disease as well as other diseases such as osteoporosis, and cognitive decline and dementia. The physiologic effects of exogenous estrogen are compatible with a cardioprotective effect. Estrogen reduces LDL and increases HDL levels; reduces Lp(a), plasminogen activator inhibitor type 1, and insulin levels; inhibits oxidation of LDL; and improves endothelial vascular function. Estrogen has complex effects on inflammation: Levels of fibrinogen decrease, whereas levels of hsCRP increase. Many of these effects are greatest with oral estrogen and minimal with transdermal estrogen, suggesting a first-pass effect at the level of the liver. Estrogen also may improve glucose tolerance.

Interventions of Hormone Therapy for Cardioprotection

Although the observational study data among women who began hormone therapy around the time of menopause consistently suggested coronary heart disease benefits of hormone replacement therapy, the randomized trial data has not demonstrated that estrogen and progestin replacement confers cardioprotection, especially among older women. The NHLBI WHI, including two large-scale, long-term randomized trials of hormone therapy, evaluated the role of hormone therapy in the prevention of cardiovascular disease, as well as assessing the balance of benefits and risks of hormone therapy when used for chronic disease prevention. For many outcomes, the WHI is the only large, long-term randomized trial of postmenopausal women using hormone therapy.

One arm of the WHI evaluated the relative benefits and risks of combined hormone therapy of conjugated estrogen plus medroxyprogesterone acetate versus placebo among 16,608 postmenopausal women, 50 to 79 years of age, with an intact uterus at baseline during a planned 8-year period. After a mean follow-up period of 5.2 years, however, the trial's Data and Safety Monitoring Board recommended stopping the trial 3 years early because the overall risk-to-benefit ratio of estrogen-progesterone therapy was unfavorable. Risks in the hormone therapy group in terms of increases in coronary heart

disease, stroke, venous thromboembolism, and breast cancer exceeded the benefits on reductions of fracture and colon cancer.¹⁸³ The estimated hazard ratios were 1.29 (95% CI, 1.02 to 1.63) for coronary heart disease, 1.41 (1.07 to 1.85) for stroke, and 2.13 (1.39 to 3.25) for pulmonary embolism. The hazard ratio for total cardiovascular disease was 1.22 (1.09 to 1.36). The absolute excess cardiovascular risks per 10,000 person-years attributable to estrogen plus progestin were 7 more coronary heart disease events, 8 more strokes, and 18 more pulmonary emboli, with 8 more breast cancers, 6 fewer colorectal cancers, and 5 fewer hip fractures (Fig. 42-30).

The increased risk of cardiovascular disease and adverse risk-to-benefit ratio was unexpected, and seemed apparently inexplicable in the face of the existing body of literature supporting the concept that hormone therapy was cardioprotective. After the release of these results, hormone therapy prescriptions abruptly and dramatically declined, because hormone therapy was no longer being initiated for the prevention of coronary heart disease. Two years later, the unopposed estrogen-versus-placebo arm of the WHI, which included 10,739 generally healthy postmenopausal women 50 to 79 years of age without a uterus, also was halted early because of an increased risk of stroke, particularly in subjects 60 years of age or older, in the absence of net health benefits.²³⁴ After a mean period of 6.8 years of follow-up, the use of estrogen was associated with a 39% increase in incidence of stroke, a 9% reduction in coronary heart disease, and a 30% to 39% reduction in fracture rate.

The discrepancies between the observational study results and the randomized trial findings led to a careful examination of how the clinical trials may have differed from the observational studies in ways that may have affected the results. Detailed scrutiny of subgroups of the trial data raised a number of unanswered questions about the role of estrogens and other hormones in the biology and etiology of cardiovascular disease and suggested that age and time since menopause may in fact modulate the effect of estrogen on cardiovascular risk.^{235,236} The WHI trials demonstrated a number of demographic and biologic differences from the observational studies that limited generalizing the findings to all postmenopausal women. These differences included the use of only one route of administration (oral), only one formulation of estrogen (conjugated estrogens) and only one progestogen (medroxyprogesterone acetate). Perhaps most important, the WHI and the observational studies were conducted in different populations: The WHI enrolled generally healthy postmenopausal women aged 50 to 79 years in a prevention trial, whereas participants in the observational studies were primarily relatively young and symptomatic women who began hormone therapy early in menopause. Secondary analyses of the WHI suggested that the disparity in findings related in part to the timing of initiation of hormone therapy in relation

FIGURE 42-30 The Women's Health Initiative, July 2002: Initial results from the combined therapy arm of the trial. CEE = conjugated equine estrogen; MPA = medroxyprogesterone acetate; VTE = venous thromboembolism. (From Stuenkel CA: *Management of menopausal symptoms in the post-Women's Health Initiative era*. In Goldman MB, Troisi R, Rexrode KM [eds]: *Women and Health*. 2nd ed. San Diego, Academic Press, 2013.)

to age and proximity to menopause,²³⁷ with WHI participants being on average 63 years of age and more than 10 years beyond menopause, whereas the observational study participants were younger than 55 years of age at the time hormone therapy was initiated and within 2 to 3 years of menopause. When the relevant data were analyzed by age and time since menopause, the estrogen arm of the WHI appeared to be more in general agreement with the observational studies suggesting that estrogen therapy may reduce coronary heart disease risk when initiated in younger and more recently postmenopausal women without a uterus. Further analyses indicated that women who start hormone therapy more than 10 years beyond menopause had increased risk for coronary heart disease, but those women in whom heart disease was diagnosed within 10 years of menopause tended to have a lower risk for coronary heart disease.

The WHI provided clear evidence that postmenopausal hormone therapy did not prevent coronary disease in women who started treatment distant from menopause onset. Yet the question remained of whether estrogen therapy initiated close to menopause onset may reduce coronary heart disease risk. Two trials addressed the issue of timing of initiation of hormone therapy in terms of atherosclerosis progression using noninvasive imaging, and the possible effects of nonoral estrogen: the ongoing Early Versus Late Intervention Trial with Estradiol (ELITE)²³⁸ and the Kronos Early Estrogen Prevention Study (KEEPS). KEEPS was a 4-year randomized, double-blind, placebo-controlled trial of low-dose oral conjugated equine estrogens (CEE) or transdermal estradiol (E2) and cyclic monthly progesterone in 727 healthy women (mean age, 52 years) who were within 3 years after menopause at randomization.²³⁹ Hormone treatment had many favorable effects in newly menopausal women: decrease in menopausal symptoms, depression, and anxiety; increase in HDL (with oral CEE); and improvement of insulin sensitivity (with transdermal E2), with no significant differences in frequency of adverse events including diagnosis of breast cancer, endometrial cancer, MI, stroke, transient ischemic attack (TIA), and venous thromboembolic disease, although the absolute numbers of such events were extremely small. Although the data were reassuring that no increases in cardiac risk occurred during this short-term use of hormone therapy, neither hormone regimen significantly reduced or accelerated progression of atherosclerosis as measured by arterial imaging.²⁴⁰

Because of its risks, many professional organizations have recommended against the use of hormone therapy at any age to prevent coronary heart disease and other chronic diseases, including the U.S. Preventive Services Task Force, the American College of Obstetrics and Gynecology, the AHA, and the Canadian Task Force on Preventive Health Care. The FDA has revised the labeling for all postmenopausal hormone therapies containing estrogen alone or estrogen plus a progestogen to include a boxed warning that highlights the increased risk for heart disease, MI, stroke, and breast cancer. Because the only way to test definitively the timing hypothesis would be to conduct a randomized trial of women enrolled close to menopause with clinical outcomes, the reality of the low event rates, the necessary large size of the trial and extended length of follow-up, the feasibility with regard to costs and adherence, and the requisite ethical issues that must be considered suggest that it is unlikely that new data will emerge soon to change these recommendation.²³⁵

Hormone therapy retains a role in clinical practice for the treatment of moderate to severe menopausal symptoms.²⁴¹ Constructing an individual risk-benefit ratio is of key importance, incorporating the woman's health and quality of life priorities as well as her risk of various disease outcomes. In a reassessment of the evidence-based position statement published by the North American Menopause Society in 2010 regarding recommendations for hormone therapy for postmenopausal women, the Society's 2012 Hormone Therapy Position Statement²⁴² concluded that current evidence supports the initiation of hormone therapy around the time of menopause to treat menopause-related symptoms and to prevent osteoporosis in women at high risk of fracture. Hormone therapy carries a low absolute risk in healthy women 50 to 59 years of age, whereas long-term hormone therapy or hormone therapy initiation in older women is associated with greater risks. The Society's recommendation for duration of

therapy differed between combined estrogen and estrogen alone therapy. The more favorable benefit-to-risk ratio for estrogen therapy allows more flexibility in extending the duration of use compared with combined estrogen-progestogen therapy, for which the earlier appearance of increased breast cancer risk precludes a recommendation for estrogen-progestogen use beyond 3 to 5 years.

Community-Based and Multiple Risk Factor Intervention Programs

Despite interventions aimed at individual patients, the burden of cardiovascular disease continues to grow (see Chapter 1). In the United States, more than 2 million heart attacks and strokes occur annually, and cardiovascular disease remains the leading cause of death, with related medical and productivity losses estimated to exceed \$450 billion each year.³⁵ Worldwide, coronary heart disease and stroke are now the top two causes of death even in economically developing countries, where the number of deaths from complications of atherosclerosis now exceeds deaths resulting from infection and malnutrition.

In an effort to address this burden domestically, several groups including the Department of Health and Human Services have launched the "Million Hearts" initiative to prevent 1 million heart attacks and strokes over the next 5 years in the United States.²⁴³ This initiative takes two complementary approaches, one clinical and one community-based. For individual patients, Million Hearts targets the "ABCS"—aspirin for high-risk patients, blood pressure control, cholesterol reduction, and smoking cessation. At the community level, Million Hearts endorses policies for sodium restriction and the elimination of artificial trans fats from the diet, along with implementing policies and programs designed to dramatically lower cigarette consumption and

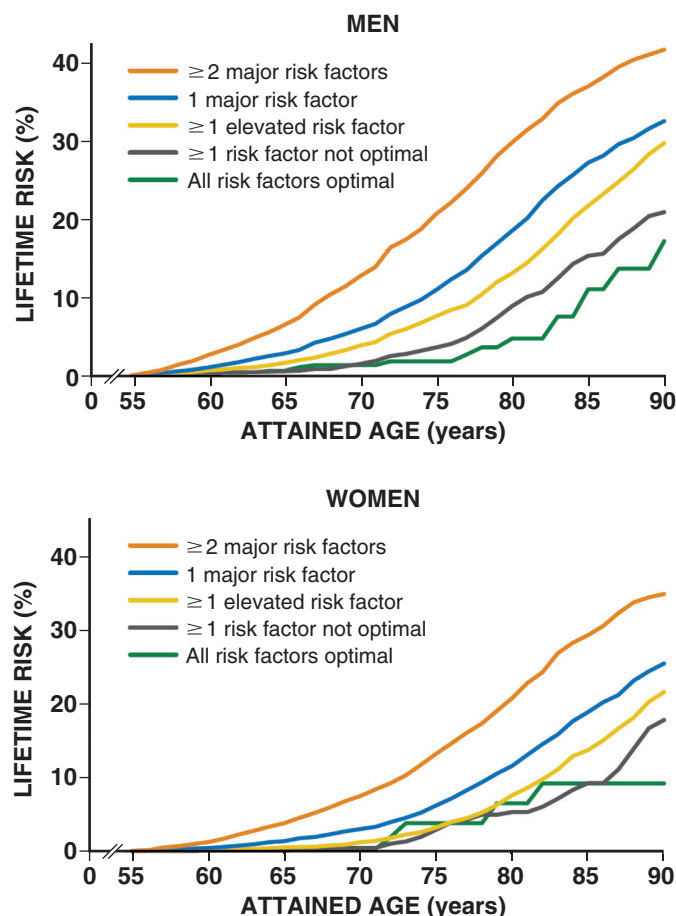

FIGURE 42-31 Lifetime risk of death from cardiovascular disease among men (top) and women (bottom) at 55 years of age, according to the aggregate burden of risk factors, and adjusted for competing risks of death. (From Berry JD, Dyer A, Cai X, et al: Lifetime risks of cardiovascular disease. *N Engl J Med* 366:321, 2012.)

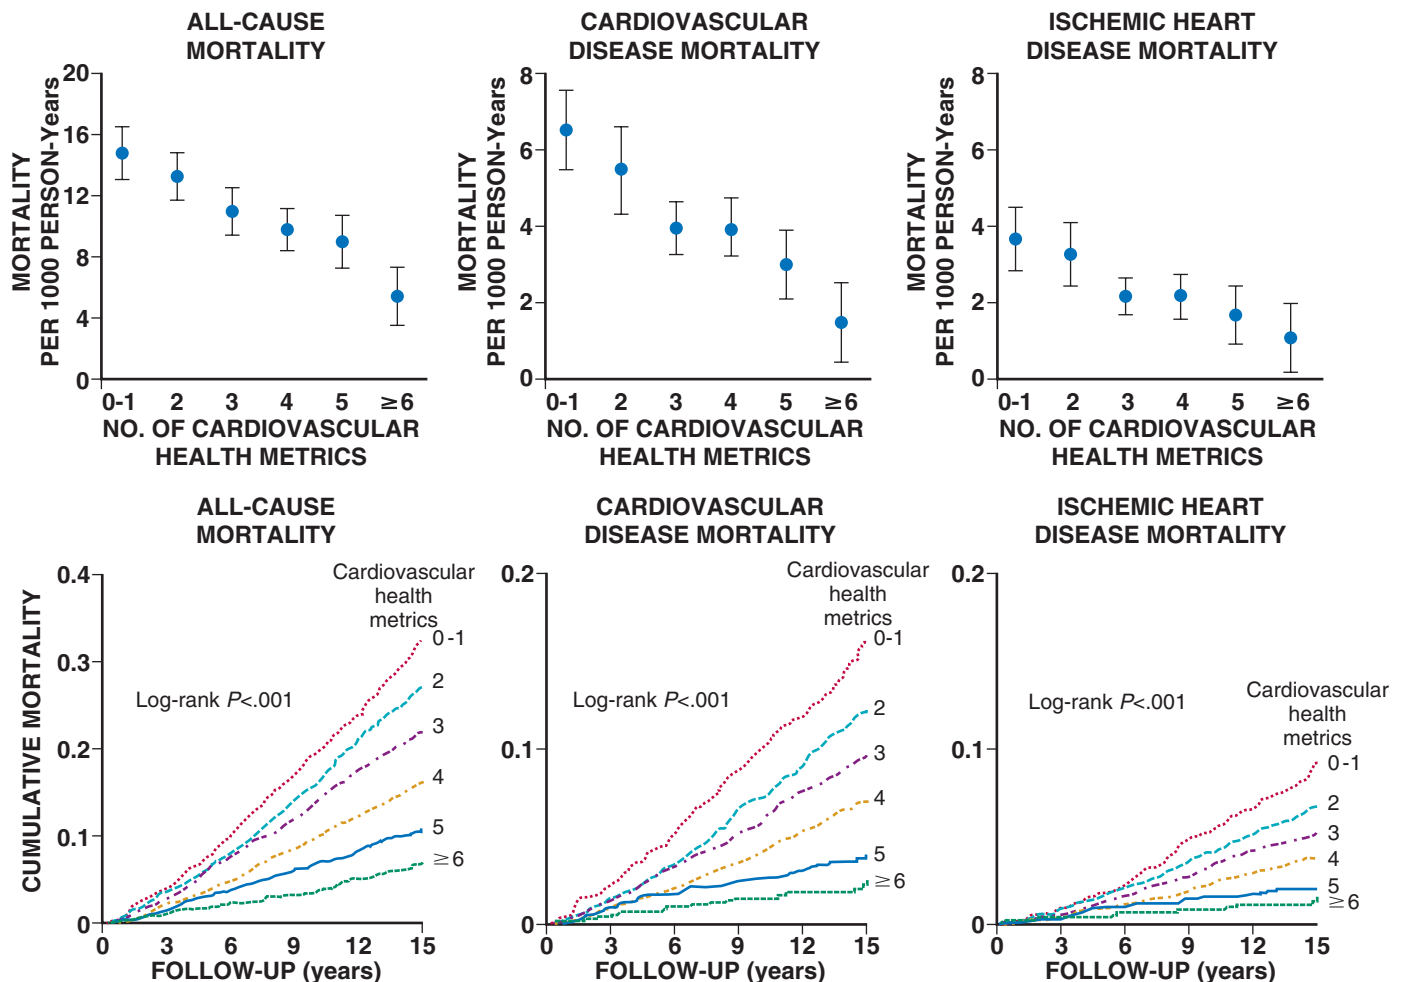

FIGURE 42-32 Age- and sex-standardized mortality rates (top row) and Kaplan-Meier curves (bottom row) for all-cause mortality, cardiovascular mortality, and ischemic heart disease mortality according to number of cardiovascular health metrics achieved. (From Yang Q, Cogswell ME, Flanders WD, et al: Trends in cardiovascular health metrics and associations with all-cause and CVD mortality among US adults. *JAMA* 307:1273, 2003.)

exposure to secondhand smoke. The initiative also emphasizes programs designed to increase community access to exercise facilities and to programs that target weight reduction and nutrition.

Past success in federally sponsored programs that limit tobacco advertising and that mandate food labeling supports the efficacy of such community-based approaches. Innovations in coverage for preventive care require consideration. In a recent North American trial, the elimination of copayments for preventive medications improved adherence without increasing overall health care costs.²⁴⁴ Cluster-randomized trials also have shown the feasibility of implementing multifaceted interventions using evidence-based therapies in developing economies.²⁴⁵ Changes in living environments and urban design can have a favorable impact on vascular health of populations, as in the case of pollution control.²⁴⁶

Community-based interventions have particular relevance to prevention in addressing lifetime risk rather than 10-year risk. As recently shown in meta-analysis of 18 cohort studies involving 257,000 persons across the United States, those with “optimal” risk factor profiles had substantially lower risks of death from cardiovascular disease up to 80 years of age, as compared with those with two or more major risk factors. Those with controlled risk factors also had markedly lower lifetime risks of fatal coronary heart disease or nonfatal infarction as well as of fatal and nonfatal stroke³ (Fig. 42-31). These effects maintained consistency across birth cohorts and ethnic groups and between men and women. Lifetime risk estimates thus suggest that efforts to lower the burden of cardiovascular disease moving forward will require prevention of the development of risk factors (primordial prevention) in concert with treatment of established risk factors (primary prevention).

Evidence supports the achievability of improvements on a population level. American youths²⁴⁷ and adults²⁴⁸ have shown favorable trends in lipid levels over the past decade. By contrast, over the same period, the prevalence of obesity in the United States has not decreased,²⁰¹ and the prevalence of major cardiovascular risk factors remains particularly high among minority groups.²⁴⁹

Recently, the AHA encouraged the U.S. population to meet seven cardiovascular health metrics: not smoking, being physically active, having normal levels of blood pressure, glucose, cholesterol, and weight, and eating a healthy diet. These simplified metrics, easily introduced in the primary care office as well as in community wellness centers, correlate closely with all-cause mortality, cardiovascular mortality, and ischemic heart disease mortality²⁵⁰ (Fig. 42-32). Hence the reduction to practice of the precepts and evidence base reviewed in this chapter and related chapters could produce prodigious public health benefits worldwide.

GUIDELINES

Management of Lipids

Paul M Ridker, Peter Libby, and Julie E. Buring

In late 2013, the American Heart Association and American College of Cardiology (AHA/ACC) released new guidelines for risk assessment and the use of statin therapy to prevent cardiovascular events.^{1,2} Recent European and Canadian guidelines have also been issued.^{3,4} Several aspects of the new AHA/ACC guidelines represent important advances, including the recognition that statin therapy reduces stroke events, that non-statin LDL-lowering agents have not yet been proven effective at reducing vascular risk, and that virtually all individuals with a history of atherosclerotic disease merit consideration for higher intensity statin regimens. Further, the new guidelines move away from LDL targets, recognizing the lack of firm data to support such an approach.⁵ Additionally, the guideline recommends engaging the patient in discussion regarding treatment options, recognizing personal choices that may influence management.

The new guideline defined four major statin benefit groups (**Table 42G-1**). This guideline defined three categories of intensity of statin therapy (**Table 42G-2**). The guideline considered high-intensity statin therapy a daily dose that lowers LDL-C by 50% or more and moderate-intensity a dose that achieves a reduction of at least 30% but less than 50%.

The guideline provided flow chart algorithms for statin treatment in primary (**Figure 42G-1**) and secondary (**Figure 42G-2**) prevention.

TABLE 42G-1 Major Statin Benefit Groups

- Clinical ASCVD “secondary prevention”
- LDL-C ≥ 190 mg/dL without secondary cause (e.g., high saturated/trans fats, drugs)
- Primary prevention *with* diabetes—
Age 40-75 years—LDL-C 70-189 mg/dL
- Primary prevention—*without* diabetes—
Age 40-75 years—LDL-C 70-189 mg/dL, estimated ASCVD risk using a new Pooled Cohort algorithm $\geq 7.5\%$

The guideline also provided some very useful practical suggestions for managing “statin intolerance.” It recommends obtaining a history of prior or current muscle symptoms to establish a baseline before initiating statin therapy to avoid unnecessary discontinuation of statins. Many physicians will give an “exercise prescription” 4 to 6 weeks prior to a statin prescription to ensure that muscle pains resulting from initiating exercise are not attributed erroneously to the initiation of pharmacologic treatment. If unexplained *severe* muscle symptoms or fatigue develop during statin therapy, the guideline recommendations state that the statin be promptly discontinued and that the possibility of rhabdomyolysis be addressed by laboratory testing. If *mild-to-moderate* muscle symptoms develop during statin therapy, the panel recommends discontinuation of the statin during investigation. The guideline suggests evaluation of the patient for other conditions that may increase the risk for muscle symptoms, including hypothyroidism, reduced renal or hepatic function, or rheumatologic disorders such as polymyalgia rheumatica, steroid myopathy, vitamin D deficiency, or primary muscle diseases. If after 2 months without statin therapy, muscle symptoms or elevated creatine kinase levels do not resolve completely, the guideline recommends consideration of other causes of muscle symptoms.

The new guidelines have generated some controversy.⁶⁻⁸ Employing a new risk prediction algorithm, the ACC/AHA guidelines recommend “a discussion” regarding statin therapy in primary prevention among those with a predicted 10-year risk of greater than or equal to 7.5% and “consideration of a discussion” regarding statin therapy among those with 10-year risks between 5% and 7.5%.¹ Application of the new risk algorithm to some samples has indicated systematic overestimation of risk.^{6,9,10} Part of this overestimation appears to be due to reliance on noncontemporary cohorts for algorithm derivation, an issue that can be addressed through recalibration. In one of the studies where calibration overall was initially poor, agreement between predicted and observed rates was improved when the population was limited to those who might benefit from statin therapy.¹⁰

Considering some of the developments in the recent guidelines from the AHA/ACC, Europe, and Canada indicates that appropriate lipid management in primary prevention cannot rely solely on any simple algorithm or box-like clinical formulation. Rather, primary prevention must take into account a complex calculus that includes knowledge of benefits and risks from the actual trials that provide evidence, along with respectful interpretation of patient preferences. Moving forward, as suggested in the 2013 AHA/ACC guideline,

TABLE 42G-2 Categories of Intensity of Statin Therapy*

HIGH-INTENSITY STATIN THERAPY	MODERATE-INTENSITY STATIN THERAPY	LOW-INTENSITY STATIN THERAPY
Daily dose lowers LDL-C by approximately $\geq 50\%$ on average	Daily dose lowers LDL-C by approximately 30% to $<50\%$ on average	Daily dose lowers LDL-C by $<30\%$ on average
Atorvastatin (40[†])-80 mg	Atorvastatin 10 (20) mg	<i>Simvastatin 10 mg</i>
Rosuvastatin 20 (40) mg	Rosuvastatin (5) 10 mg	Pravastatin 10-20 mg
	Simvastatin 20-40 mg[‡]	Lovastatin 20 mg
	Pravastatin 40 (80) mg	<i>Fluvastatin 20-40 mg</i>
	Lovastatin 40 mg	<i>Pitavastatin 1 mg</i>
	<i>Fluvastatin XL 80 mg</i>	
	Fluvastatin 40 mg bid	
	<i>Pitavastatin 2-4 mg</i>	

Specific statins and doses that are noted in **bold** were evaluated in RCTs (17, 18, 46-48, 64-67, 69-78) included in CQ1, CQ2, and the CTT 2010 meta-analysis included in CQ3 (20). All of these RCTs demonstrated a reduction in major cardiovascular events. Statins and doses that are approved by the U.S. Food and Drug Administration (FDA) but were not tested in the RCTs reviewed are listed in *italics*.

*Individual responses to statin therapy varied in the RCTs and should be expected to vary in clinical practice. There might be biologic basis for a less-than-average response. [†]Evidence from 1 RCT only; down-titration if unable to tolerate atorvastatin 80 mg in IDEAL (47).

[‡]Although simvastatin 80 mg was evaluated in RCTs, initiation of simvastatin 80 mg or titration to 80 mg is not recommended by the FDA because of the increased risk of myopathy, including rhabdomyolysis.

Bid = twice daily; IDEAL = Incremental Decrease in Risk through Aggressive Lipid Lowering Study; LDL-C = low-density lipoprotein cholesterol; RCTs = randomized controlled trials. From Stone NJ, Robinson J, Lichtenstein AH, et al: 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2013.

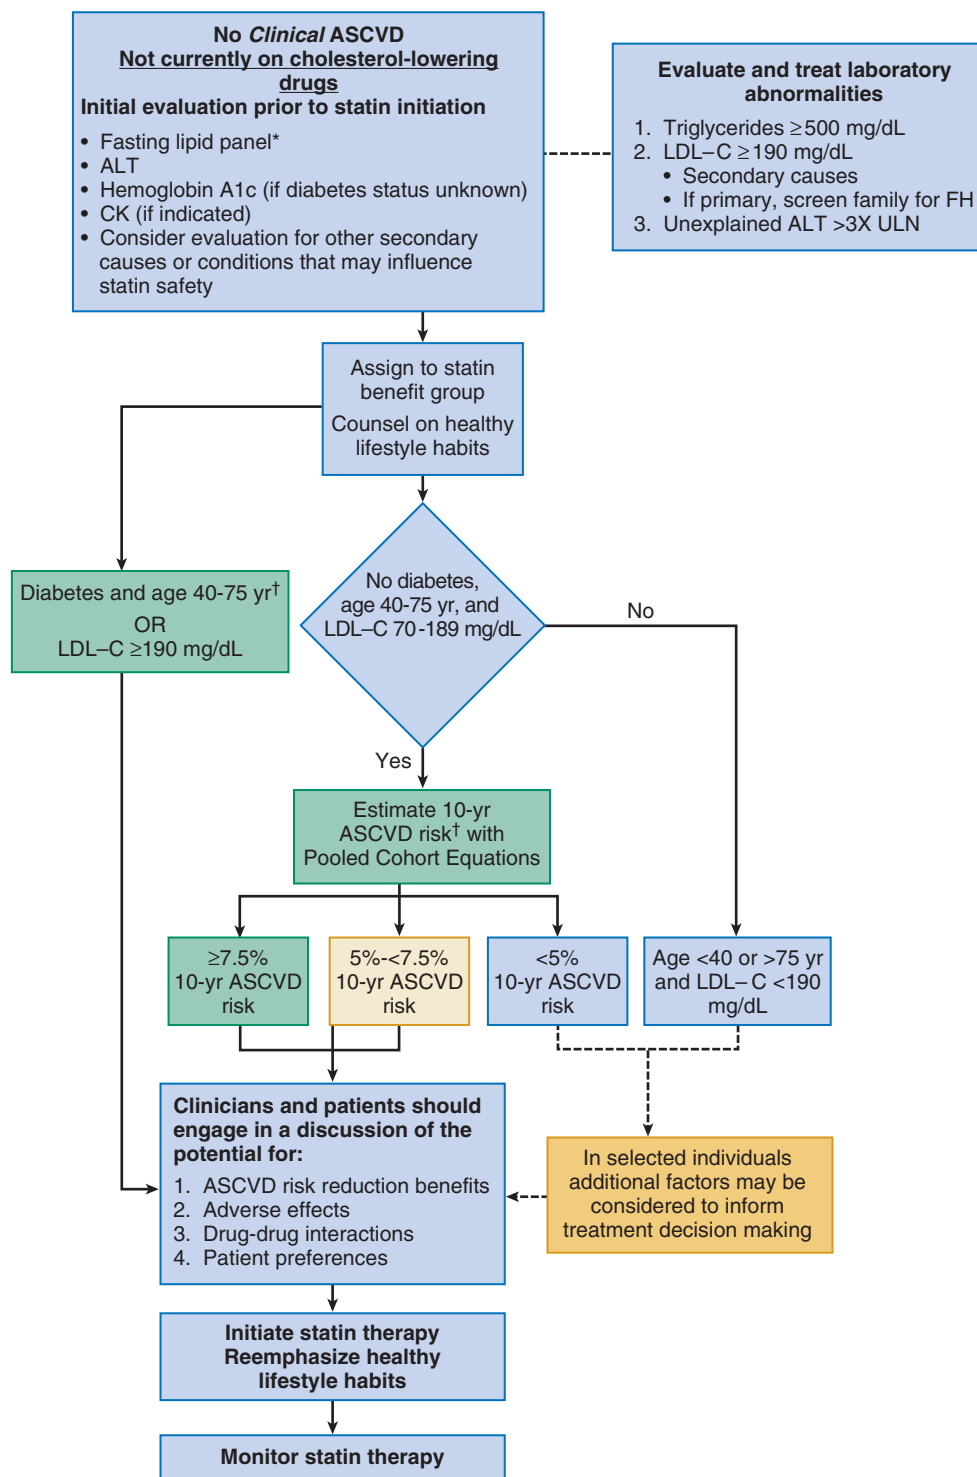

FIGURE 42G-1 Initiating statin therapy in individuals without clinical ASCVD. *Fasting lipid panel preferred. In a nonfasting individual, a nonfasting non-HDL-C >220 mg/dL may indicate genetic hypercholesterolemia that requires further evaluation or a secondary etiology. If nonfasting triglycerides are >500 mg/dL, a fasting lipid panel is required. †The Pooled Cohort Equations can be used to estimate 10-year ASCVD risk in individuals with and without diabetes. (Modified from Stone NJ, Robinson J, Lichtenstein AH, et al: 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2013.)

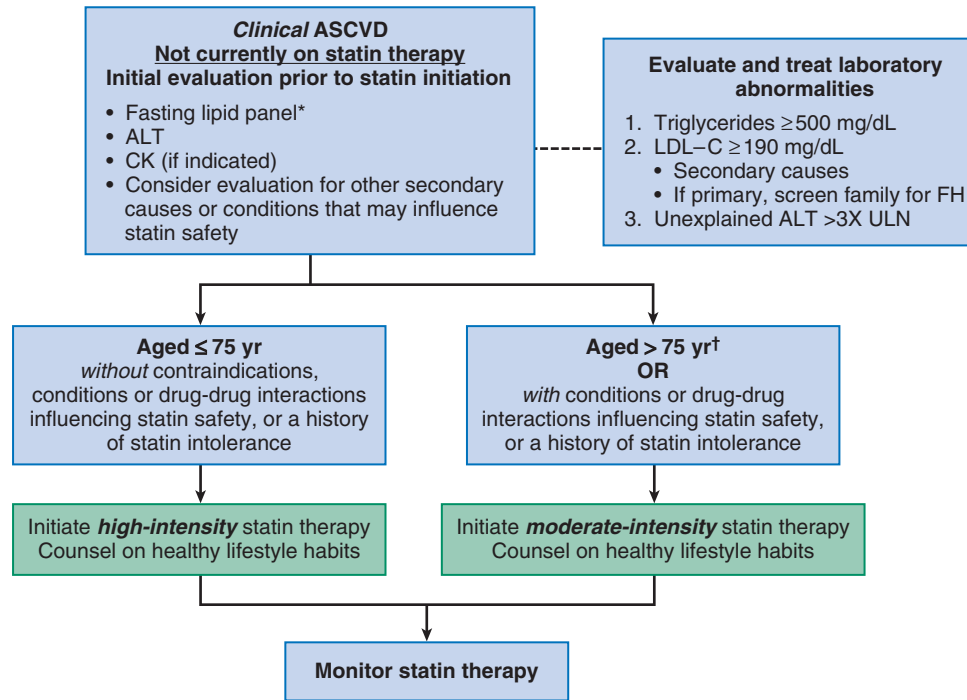

FIGURE 42G-2 Initiating statin therapy in individuals with clinical ASCVD. Colors correspond to the class of recommendations in the ACC/AHA Table 1. *Fasting lipid panel preferred. In a nonfasting individual, a nonfasting non-HDL-C >220 mg/dL may indicate genetic hypercholesterolemia that requires further evaluation or a secondary etiology. If nonfasting triglycerides are >500 mg/dL, a fasting lipid panel is required. †It is reasonable to evaluate the potential for ASCVD benefits and for adverse effects, and to consider patient preferences, in initiating or continuing a moderate- or high-intensity statin in individuals with ASCVD >75 years of age. ALT = alanine transaminase; ASCVD = atherosclerotic cardiovascular disease; CK = creatine kinase; FH = familial hypercholesterolemia; LDL-C = low-density lipoprotein cholesterol; ULN = upper limit of normal. (Modified from Stone NJ, Robinson J, Lichtenstein AH, et al: 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2013.)

physicians should recognize that the new guidelines do not predicate hard and fast rules, but are only suggestions to guide management and conversations with patients.¹¹

DEFINITION, PREVALENCE, VARIABILITY, AND DETERMINANTS OF HYPERTENSION

Affecting 75 million people in the United States and 1 billion worldwide, hypertension remains the most common, readily identifiable, and reversible risk factor for myocardial infarction (MI), stroke, heart failure, atrial fibrillation, aortic dissection, and peripheral arterial disease (see also Chapters 1 and 42). The global burden of hypertension is rising owing to escalating obesity and population aging, and the condition is projected to affect 1.5 billion persons—one third of the world's population—by 2025. The prevalence of hypertension is increasing rapidly in developing countries, where poor hypertension treatment and control contribute to the growing epidemic of cardiovascular disease.¹ High blood pressure currently causes two thirds of all strokes and half of all cases of ischemic heart disease worldwide.² Half of this disease burden occurs in people with hypertension (i.e., blood pressure $\geq 140/90$ mm Hg); the other half occurs in people with lesser degrees of high blood pressure (prehypertension). Thus high blood pressure remains the leading cause of death worldwide and one of the world's great public health problems (see Chapter 1).

The asymptomatic nature of this condition delays diagnosis. Effective treatment requires continuity of care by a knowledgeable clinician and frequent medical checkups, which are less common in men and in members of low-income minority groups.³ Most patients diagnosed with hypertension do not manifest a single disease-causing mechanism. Treatment therefore remains empirical, often requiring three or more pharmacologic agents with complementary mechanisms of action along with lipid-lowering drugs, antiplatelet drugs, and drugs for concomitant medical conditions such as diabetes. Pill burden, prescription drug costs, medication side effects, and insufficient time for patient education contribute to medication nonadherence. Physicians often undertreat hypertension (see Chapter 44).⁴ For all of these reasons, blood pressure remains elevated—140/90 mm Hg or higher—in more than half of affected persons in the United States⁵ and other developed countries.

Even among patients whose hypertension control meets current standards, fewer than one in three is protected from subsequent stroke, MI, or heart failure. The resultant annual cost to the U.S. health care system exceeds \$73 billion, yielding a global health care cost of some \$3.6 trillion.^{6,7} This chapter and Chapter 44 review the scientific basis for current recommendations for the diagnosis, evaluation, and treatment of hypertension and present emerging concepts from clinical and basic research that affect clinical decision making.

Definition

Hypertension is defined as a usual office blood pressure of 140/90 mm Hg or higher.⁸ Yet epidemiologic data show continuous positive relationships between the risk of coronary artery disease (CAD) and stroke deaths with systolic or diastolic blood pressure down to values as low as 115/75 mm Hg⁹ (Fig. 43-1). The artificial dichotomy between “hypertension” and “normotension” may delay medical treatment until irreversible compromise of vascular health by elevated blood pressure values previously considered normal. On the other hand, the current body of evidence from randomized controlled trials does not permit experts to achieve consensus on whether to recommend blood pressure-lowering medications for high-risk patients with blood pressure in the “prehypertensive” range of 120 to 139/80 to 89 mm Hg.

Prevalence

In the United States and other developed countries, the prevalence of hypertension increases with age—rising exponentially after 30 years of age (see Chapter 1). Before 50 years of age, women have a somewhat lower prevalence of hypertension than men. After menopause, the prevalence of hypertension increases rapidly in women and surpasses that in men. Eventually, by 75 years of age—below the average life span of U.S. men and women—almost 90% will have hypertension.

More than 40% of non-Hispanic black adults in the United States have hypertension, compared with 25% of non-Hispanic white and Hispanic adults. Black Americans also have earlier onset and more severe hypertension and suffer greater target organ damage, leading to greater premature disability and death. Hypertension and its complications are even more prevalent in many predominantly white European countries than in black Americans but far less prevalent among black Africans¹⁰ (Fig. 43-2). Hypertension prevalence does not vary between black and non-black Hispanic adults in Cuba. Although genetic factors may explain the disproportionate burden of hypertension in black Americans, these international data underscore the importance of environment. From 90% to 95% of hypertensive patients have no apparent single reversible cause of elevated blood pressure, hence the term primary hypertension. The remaining 5% to 10%—cases designated as secondary or identifiable hypertension—demonstrate a more discrete mechanism.

Blood Pressure Variability and Its Determinants

Behavioral Determinants

In most patients with primary hypertension, readily identifiable behaviors contribute to the elevated blood pressure. The nicotine in

FIGURE 43-1 Absolute risks of coronary artery disease mortality (left) and stroke mortality (right) for each decade of life (plotted on a logarithmic scale) by usual systolic blood pressure level (plotted on a linear scale). CI = confidence interval. (From Lewington S, Clarke R, Qizilbash N, et al: Age-specific relevance of usual blood pressure to vascular mortality: A meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet* 360:1903, 2002.)

FIGURE 43-2 Geographic variation in hypertension prevalence in populations of African descent (pink bars) and European descent (blue bars). (Modified from Cooper RS, Wolf-Maier K, Luke A, et al: An international comparative study of blood pressure in populations of European vs. African descent. *BMC Med* 3:2, 2005.)

cigarette smoke transiently raises blood pressure by 10 to 20 mm Hg, thereby elevating the average daytime blood pressure in habitual smokers. Moderate alcohol drinkers (one or two drinks per day) generally have less hypertension than teetotalers, but the risk for development of hypertension increases in heavy drinkers (three or more drinks per day). Hypertension is rare in Asian men who abstain from alcohol to avoid the nausea and flushing reaction associated with their loss-of-function mutation in the alcohol dehydrogenase gene (*ALDH2*).^{11,12} Caffeine consumption typically causes only a

small transient rise in blood pressure, which in some persons habituates after the first cup of coffee. The risk for development of hypertension does not vary with coffee consumption but increases steeply when caffeine is consumed in diet sodas; thus coffee may contain protective antioxidant polyphenols not present in sodas. Physical inactivity also increases the risk for developing hypertension.

Lifetime dietary habits clearly influence the risk for developing hypertension (see Chapters 44 and 46). Diets low in fresh fruit may increase risk, but excessive consumption of calories and sodium are the two most important behavioral determinants of hypertension. Across various populations, hypertension prevalence increases linearly with average body mass index. Currently, up to 50% of all cases of hypertension may result from obesity. The risk for developing hypertension increases with dietary sodium intake and decreases with dietary potassium intake.¹³ Individual variability in blood pressure responses to dietary sodium loading and sodium restriction indicates an important genetic underpinning.

Genetic Determinants

Concordance of blood pressure is higher in families than in unrelated persons, higher for monozygotic than for dizygotic twins, and higher among biologic than among adoptive siblings living in the same household. As much as 70% of the familial aggregation of blood pressure may result from shared genes rather than to shared environment (see Chapter 8).

The complex regulation of blood pressure has thwarted the genetic dissection of primary human hypertension. Although mutations in 20 salt-handling genes cause ultrarare monogenic forms of severe early-onset hypotension (salt-wasting syndromes) and hypertension (all inherited as mendelian traits), applicability to common primary hypertension has proved elusive. Data from the Framingham Heart Study indicate that 1% to 2% of the general adult population has gene mutations underlying the pediatric salt-wasting syndromes (Bartter and Gitelman syndromes) that may confer resistance against primary hypertension¹⁴ (Fig. 43-3). World-wide research consortia of genome-wide association studies confirmed eight loci for blood pressure, but the individual effect size for each is so small that together these loci explain less than 1% of blood

pressure variance. The large gap between estimated and observed variance—termed “missing heritability”—could be due in part to “epigenetics,” which refers to the inheritance of gene expression patterns not strictly dependent on differences in DNA sequence.¹⁵

MECHANISMS OF PRIMARY (ESSENTIAL) HYPERTENSION

Hemodynamic Subtypes

Primary hypertension falls into three distinctly different hemodynamic subtypes that vary sharply by age.

Systolic Hypertension in Teenagers and Young Adults

Typically associated with hypertension in the elderly (see later), isolated systolic hypertension (ISH) also is the main type in young adults

FIGURE 43-3 Reduced prevalence of hypertension among mutation carriers. Prevalence of hypertension at the last examination within ages 25 to 40, 41 to 50, and 51 to 60 years, for mutation carriers and noncarriers of genes causing Bartter and Gitelman syndromes. The genotype relative risk (GRR) for mutation carriers is shown. (From Ji W, Foo JN, O’Roak BJ, et al: Rare independent mutations in renal salt handling genes contribute to blood pressure variation. *Nat Genet* 40:592, 2008.)

(typically 17 to 25 years of age). The key hemodynamic abnormalities are increased cardiac output and a stiff aorta, both presumably reflecting an overactive sympathetic nervous system. The prevalence may reach as high as 25% in young men, but the condition affects only 2% of young women. Several recent studies show that young persons with ISH have elevated central as well as brachial systolic blood pressures, indicating significantly increased hemodynamic burden.¹⁶ Thus ISH in youth may predispose to diastolic hypertension in middle age.

Diastolic Hypertension in Middle Age

Hypertension diagnosed in middle age (typically, 30 to 50 years of age) usually has the elevated diastolic pressure pattern, with normal systolic pressure (isolated diastolic hypertension) or elevated systolic pressure (combined systolic-diastolic hypertension). This pattern constitutes classic “essential hypertension.” Isolated diastolic hypertension is more common in men and often associates with middle-age weight gain. Without treatment, isolated diastolic hypertension often progresses to combined systolic-diastolic hypertension. The fundamental hemodynamic fault is an elevated systemic vascular resistance coupled with an inappropriately normal cardiac output. Vasoconstriction at the level of the resistance arterioles results from increased neurohormonal drive and an autoregulatory reaction of vascular smooth muscle to an expanded plasma volume, the latter because of impairment in the kidneys’ ability to excrete sodium.

Isolated Systolic Hypertension in Older Adults

After the age of 55 years, ISH (systolic blood pressure > 140 mm Hg and diastolic blood pressure < 90 mm Hg) predominates. In developed countries, systolic pressure rises steadily with age; by contrast, diastolic pressure rises until approximately 55 years of age and then falls progressively thereafter (Fig. 43-4). The resultant widening of pulse pressure indicates stiffening of the central aorta and a more rapid return of reflected pulse waves from the periphery, augmenting systolic aortic pressure (see Fig. 43-4, also see Figs. e43-1, e43-2, and e43-3).¹⁷ Accumulation of collagen (which is poorly distensible) adversely affects its ratio to elastin in the aortic wall.

ISH may represent an exaggeration of this age-dependent stiffening process, although systolic blood pressure and pulse pressure do not rise with age in the absence of urbanization (e.g., cloistered nuns). ISH is more common in women and associates prominently with heart failure with preserved systolic function, a syndrome also more prevalent in women (see Chapters 27, 76, and 77). Most cases of ISH arise de novo after 55 years of age and do not represent

FIGURE 43-4 A, Age-dependent changes in systolic and diastolic blood pressure in the United States. B, Schematic representation of the relationship between aortic compliance and pulse pressure. (A, From Burt V, Whelton P, Rocella EJ, et al: Prevalence of hypertension in the U.S. adult population. Results from the Third National Health and Nutrition Examination Survey, 1988-1991. *Hypertension* 25:305, 1995. B, From Dr. Stanley Franklin, University of California at Irvine, with permission.)

FIGURE e43-1 Central aortic pressure waveform. The height of the late systolic peak above the inflection defines the augmented pressure, and the ratio of augmented pressure to pulse pressure (PP) defines the augmentation index (expressed as a percentage). (From Agabiti-Rosei, E, Mancia G, O'Rourke MF, et al: *Central blood pressure measurements and antihypertensive therapy: A consensus document. Hypertension* 50:154, 2007.)

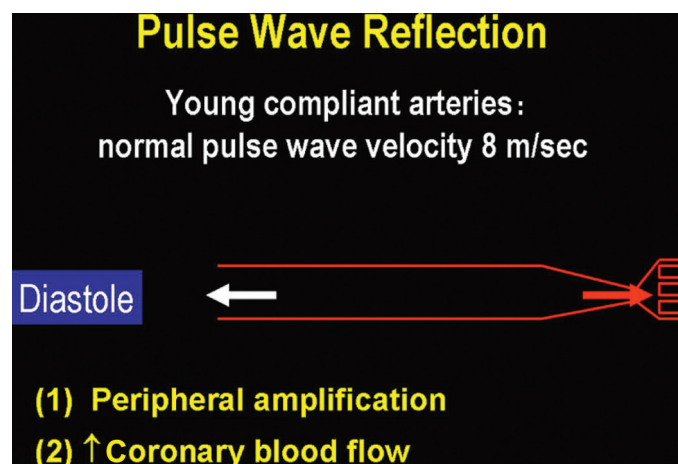

FIGURE e43-2 An artist's rendering of normal pulse wave velocity and the timing of the reflected wave. In a young person with compliant arteries, pulse wave velocity is 8 meters/sec. The reflected pulse wave reaches the central aorta in diastole, thereby amplifying central diastolic pressure and hence coronary perfusion pressure. (Courtesy Dr. Stanley Franklin, University of Calif, Irvine, Calif.)

FIGURE e43-3 Artist's rendering of increased pulse wave velocity in ISH and resultant changes in central aortic pressure and hemodynamic load. In an elderly patient with ISH and stiff arteries, pulse wave velocity is 12 meters/sec, which is abnormally fast. The reflected pulse wave reaches the central aorta in systole, thereby amplifying central systolic pressure and widening the central pulse pressure. The augmented aortic systolic pressure accelerates the development of LVH, increases myocardial oxygen demand (MVO_2), and accelerates endothelial dysfunction and atherosclerosis. The rapid diastolic runoff can compromise coronary perfusion pressure, thereby predisposing the patient to development of subendocardial ischemia. BP = blood pressure. (Courtesy Dr. Stanley Franklin, University of California, Irvine, Calif.)

“burned-out” middle-age diastolic hypertension; more than 80% of patients with isolated diastolic hypertension, however, will develop ISH in the next decade of life.¹⁶ Compared with young or middle-aged adults with optimal blood pressure, those with pressures in the high-normal range (prehypertension) are more likely to develop ISH after the age of 55 years.

A multitude of neurohormonal, renal, and vascular mechanisms interact to various degrees in contributing to these different hemodynamic forms of hypertension.

Neural Mechanisms

Two invasive approaches to treat hypertension—surgical implantation of a carotid baroreceptor pacemaker and catheter-induced renal nerve ablation (see Chapter 60)—have rekindled great interest in the neural mechanisms of clinical hypertension.^{18,19} Figure 43-5 shows the major central and reflex mechanisms thought to drive sympathetic overactivity in human hypertension. These include, among others, resetting of the baroreceptors and activation of renal sensory nerves termed renal afferents. Figure 43-5 also shows the specific mechanisms that are targeted by the device-based therapies. Neither device is yet approved by the U.S. Food and Drug Administration (FDA).

The Carotid Baroreceptor Pacemaker

The Rheos system (CVRx, Inc., Minneapolis) is a surgically implanted carotid baroreceptor pacemaker.²⁰ With the patient under general anesthesia, electrode wires are implanted around the carotid sinus nerves in the neck and connected to a pacemaker generator placed

in a subcutaneous pocket in the chest. Electrical stimulation of the carotid sinus nerves sends afferent neural signals that the brainstem interprets as a rise in blood pressure, evoking a reflex reduction in blood pressure. The efferent arm of this reflex arc involves decreased efferent sympathetic nerve activity to the heart, which slows heart rate; to the peripheral circulation, which lowers systemic vascular resistance; and to the kidney, which reduces renin release and increases renal sodium excretion. Activation of the Rheos device acutely decreases sympathetic nerve activity, blood pressure, and heart rate and may avert acute hypertensive crisis.²¹ Although the carotid sinus and aortic arch baroreceptors buffer acute increases in blood pressure, data regarding the durability of the antihypertensive action of continual carotid baroreceptor stimulation are lacking. This question was addressed by the Rheos Pivotal Trial, a randomized, double-blind, placebo-controlled study of carotid baroreceptor pacing in patients with drug-resistant hypertension.²⁰

In the Rheos trial, 265 patients with resistant hypertension and baseline blood pressure averaging 169/101 mm Hg (despite treatment of most patients with five or more blood pressure medications) underwent implantation of the Rheos device and subsequently random assignment (2:1) 1 month after implantation to immediate initiation of bilateral carotid baroreceptor pacing (group A) or delayed initiation until the 6-month visit (group B); all patients received open-label baroreceptor pacing for another 6 months. The results were largely negative, but mixed. There were no group differences at 6 or 12 months in the coprimary endpoints of percentage of subjects in whom systolic blood pressure decreased by at least 10 mm Hg (54% for group A and 46% for group B; $P = \text{NS}$); and 9% of patients developed transient or permanent facial nerve injury. Yet a post-hoc analysis showed that 42% of group A patients and 24% of group B patients achieved systolic blood pressure control (systolic blood pressure ≤ 140 mm Hg) at 6 months ($P = 0.005$), with just over 50% of both groups achieving systolic blood pressure control at 12 months (at which point group B had received baroreceptor pacing for 6 months). The reduction in blood pressure associated with a small initial decrease in estimated glomerular filtration rate (eGFR).²² More research should determine if efficacy and safety can be improved by additional technical refinements or if offsetting responses from aortic baroreceptors, which are not paced, inherently limit this approach. A second-generation minimally invasive unilateral carotid nerve pacing system (Barostim neo) has yielded encouraging preliminary results for safety and efficacy.²³

FIGURE 43-5 Sympathetic neural mechanisms of blood pressure regulation and treatment targets of carotid baroreceptor pacing and renal denervation. Note that aortic baroreceptors, which also influence blood pressure, are not paced. Also note that renal denervation affects afferent and efferent renal nerves. Dotted arrows represent inhibitory neural influences, and solid arrows represent excitatory neural influences on sympathetic outflow to the heart, peripheral vasculature, and kidneys. A II = angiotensin II; ACh = acetylcholine; EPI = epinephrine; NE = norepinephrine; NTS = nucleus tractus solitarius. (Modified from Martin EA, Victor RG: Premise, promise, and potential limitations of invasive devices to treat hypertension. *Curr Cardiol Rep* 2011; 13:86-92).

Catheter-Based Renal Denervation

Rat studies have identified a major role for the renal sympathetic nerves in the development of hypertension, but the importance of the renal nerves in causing human hypertension previously has not been studied directly. Renal sympathetic nerves cause renal vasoconstriction and vascular hypertrophy via α -1 receptors, stimulate renin release via β -1 receptors, and enhance renal sodium and water reabsorption via α -1 receptors (Fig. 43-6). Thus catheter-based renal denervation is an exciting novel approach to treat patients with drug-resistant hypertension, as described and

applied in the Symplicity HTN-1 and HTN-2 trials.²⁴ Radiofrequency current delivered by way of an intraluminal catheter destroys the renal nerves, located on the adventitial surface of the renal arteries. With the patient under conscious sedation, the Symplicity catheter is advanced into each renal artery, and four to six discrete low-power radiofrequency treatments are applied along the length of each artery.

In the unblinded Symplicity HTN-2 trial (Renal Denervation in Patients with Uncontrolled Hypertension), a total of 106 non-U.S. patients with drug-resistant hypertension and baseline blood pressure of 178/97 mm Hg despite treatment with an average of five or more blood pressure medications randomly were assigned to undergo renal denervation while continuing previous drug therapy or to continue previous drug therapy alone. Patients who met initial screening criteria were excluded if systolic blood pressure fell below 160 mm Hg on a second screening or if they had unfavorable renal anatomy. The primary endpoint was the change from baseline in seated office-based measurement of systolic blood pressure at 6 months. During the intervention, a catheter was inserted into the renal arteries with the patient under conscious sedation, and four to six discrete low-power radiofrequency treatments were applied along the intraluminal length of both renal arteries; the goal was to cause thermal destruction of the renal nerves, which are located on the adventitial (outer) surface of the renal arteries. Office-based blood pressure fell dramatically by 32/12 mm Hg in the active treatment group, versus no change in the control group. The 24-hour ambulatory blood pressure, measured in less than half of patients, fell less dramatically: by 11/7 mm Hg in the active treatment group, versus no change in the control group. No major adverse events occurred.

Subsequently, smaller studies have suggested multiple ancillary benefits of renal denervation, including improvement in glycemic control, sleep apnea,^{25,26} and quality of life²⁷; regression of left ventricular mass²⁸; reduction in central aortic stiffness^{29,30}; and adjunctive treatment for atrial fibrillation.³⁰ These diverse benefits presumably derive not from destruction of efferent renal sympathetic nerve fibers but rather from destruction of renal afferent (sensory) nerves—thereby causing a global reduction in sympathetic outflow to multiple tissues and vascular beds¹⁹ (Fig. 43-7).

The new 3-year follow-up data from the open-label uncontrolled Symplicity HTN-1 trial in 88 patients show impressive sustained reductions in office blood pressure averaging $-36/-14$ mm Hg, but ambulatory blood pressure was not assessed.³¹ Renal denervation

did not prevent a decline in eGFR, but without a control group, we do not know if this decline is less than or greater than that caused by hypertension alone without renal denervation. Based on the outcomes of the randomized but open-label Symplicity HTN-2 trial, renal denervation already has been approved for clinical use in Europe, Australia, and Asia. The randomized and blinded Symplicity HTN-3 trial, however, did not show a significant reduction in office or ambulatory blood pressure 6 months post procedure compared to a sham intervention.^{31b} Thus validation of the efficacy of this procedure will require further work.

Renal denervation studies already have proven an important sympathetic neural contribution to severe drug-resistant human hypertension. Previously, the sympathetic nervous system was implicated mainly in the initiation of hypertension, but not in its maintenance. These studies also suggest a greatly expanded role of the renal afferents, formerly thought to contribute mainly in renal parenchymal hypertension and cyclosporine-induced hypertension.^{32,33}

In young adults, primary hypertension consistently associates with increased heart rate and cardiac output, plasma and urinary norepinephrine levels, regional norepinephrine spillover, peripheral postganglionic sympathetic nerve firing (determined by microelectrode recordings), and alpha-adrenergic receptor-mediated vasoconstrictor tone in the peripheral circulation.¹⁸ Sympathetic overactivity occurs in early primary hypertension and in several other forms of established human hypertension, including hypertension associated with obesity, sleep apnea, early type 2 diabetes mellitus and prediabetes, chronic kidney disease (CKD), heart failure, and immunosuppressive therapy with calcineurin inhibitors such as cyclosporine. In these conditions, central sympathetic outflow can result from deactivation of inhibitory neural inputs (e.g., baroreceptors), activation of excitatory neural inputs (e.g., carotid body chemoreceptors, renal afferents), or circulating angiotensin II (A II), which activates pools of excitatory brainstem neurons without a blood-brain barrier (see Fig. 43-5).

In hypertension, the baroreceptors reset to defend a higher level of blood pressure. Baroreflex control of sinus node function is abnormal even in mild hypertension, but baroreflex control of systemic vascular resistance and blood pressure is well preserved until diastolic function is impaired.³⁴ Complete baroreflex failure (see Chapter 89) causes labile hypertension, most often seen in throat cancer survivors as a late complication of radiation therapy, which causes a gradual destruction of the baroreceptor nerves. Partial baroreceptor dysfunction is common in elderly hypertensive patients and typically manifests with a triad of orthostatic hypotension, supine hypertension, and symptomatic postprandial hypotension—the last initiated by splanchnic pooling after carbohydrate-rich meals.

Obesity-Related Hypertension

Neural mechanisms of obesity-related hypertension deserve special mention. With weight gain, reflex sympathetic activation may be an important compensation to burn fat, but at the expense of sympathetic overactivity in target tissues (i.e., vascular smooth muscle and kidney) that produces hypertension. Hypertensive patients with the metabolic syndrome, with or without new-onset type 2 diabetes, have near-maximal rates of sympathetic firing. Although the sympathetic activation associates with insulin resistance, the precise stimulus to sympathetic outflow is unknown; candidates include leptin, other adipokines, and A II. Why weight loss improves hypertension much less than diabetes remains unknown.³⁵

Obstructive Sleep Apnea as a Cause of Neurogenic Hypertension

Patients with obstructive sleep apnea can have markedly elevated plasma and urine catecholamine levels, mimicking those seen in patients with

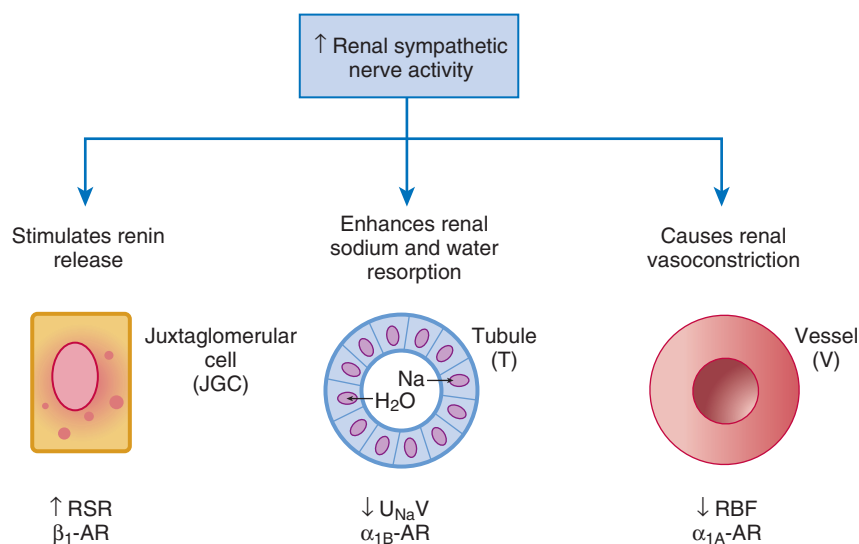

FIGURE 43-6 Effects of increased renal sympathetic nerve activity on the three renal neuroeffectors: the juxtaglomerular granular cells with increased renin secretion rate (RSR) via stimulation of the beta-1 adrenoceptors (β₁-AR); the renal tubular epithelial cells (T) with increased renal tubular sodium reabsorption and decreased urinary sodium excretion (U_{NaV}) via stimulation of alpha-1β adrenoceptors (α_{1B}-AR); and the renal vasculature (V) with decreased renal blood flow (RBF) via stimulation of α_{1A}-AR. (From DiBona GF: Physiology in perspective: The wisdom of the body. Neural control of the kidney. *Am J Physiol Regul Integr Comp Physiol* 289:R633, 2005.)

FIGURE 43-7 Conceptual framework by which denervation of renal afferents explains ancillary benefits of catheter-based renal denervation. In patients with drug-resistant hypertension, overactivity of efferent renal sympathetic nerve activity (SNA) contributes to salt-sensitive hypertension, whereas overactivity of renal sensory (afferent) nerves triggers sustained reflex increases in cardiac SNA (leading to left ventricular hypertrophy, arrhythmias, and increased oxygen consumption), in skeletal muscle SNA (leading to insulin resistance), and in splenic SNA (activating T cells, which are honed to vascular smooth muscle, stimulating reactive oxygen species [ROS] that promote vascular inflammation and atherosclerosis).

pheochromocytoma (see Chapter 81). With repeated arterial desaturation during apneas, activation of carotid body chemoreceptors causes dramatic pressor episodes throughout the night and resets the chemoreceptor reflex; daytime normoxia is misinterpreted as hypoxia, producing sustained reflex sympathetic activation and hypertension even during waking hours (see Chapter 75). Obstructive sleep apnea also accelerates the risk of several hypertensive complications (e.g., stroke, atrial fibrillation, and cardiovascular death) beyond that explained by blood pressure elevation alone.³⁶

Renal Mechanisms

The typical U.S. diet is high in NaCl, with most dietary salt coming from processed food (see also Chapter 46). Although men consume an estimated 10.7 g of NaCl daily, and women 7.3 g, the Department of Agriculture and the Department of Health and Human Services recommend a daily intake of less than 5.8 g of NaCl (2300 mg of sodium) for the general population, and 3.7 g for persons with hypertension or prehypertension. If the food industry agreed to a palatable reduction in the salt content of processed food, reducing dietary salt by 3 g per day probably would reduce the annual number of new cases of coronary heart disease by 60,000 to 120,000, new cases of stroke by 32,000 to 66,000, and new cases of MI by 54,000 to 99,000 and would reduce the annual number of deaths from any cause by 44,000 to 92,000. All segments of the population would benefit, with blacks benefiting proportionately more, women benefiting particularly from stroke reduction, older adults from reductions in coronary heart disease events, and younger adults from lower mortality rates.³⁷

In many forms of experimental and human hypertension, the fundamental abnormality is an acquired or inherited defect in the kidneys' ability to excrete the excessive sodium load imposed by a modern diet high in salt. Because humans evolved in a low-sodium/high-potassium environment, the human kidney handles poorly exposure to high sodium and low potassium. Renal sodium retention expands the plasma volume, increasing cardiac output and triggering

autoregulatory responses that increase systemic vascular resistance. Salt retention also augments the smooth muscle contraction produced by endogenous vasoconstrictors. Beyond raising blood pressure, a high-salt diet also accelerates hypertensive target organ damage.

Resetting of Pressure-Natriuresis

In normotensive persons, blood pressure elevation invokes an immediate increase in renal sodium excretion to shrink plasma volume and to return blood pressure to normal. In almost all forms of hypertension, the pressure-natriuresis curve is shifted to the right, and in salt-sensitive hypertension, the slope is reduced. Resetting of the pressure-natriuresis curve prevents the return of blood pressure to normal, so that fluid balance is maintained but at the expense of high blood pressure. It also leads to nocturia, one of the most common and bothersome symptoms in patients with uncontrolled hypertension. Hypertensive persons excrete the same amount of a given dietary sodium load as normotensive persons do, but at a higher blood pressure, and require many more hours to excrete the sodium load and to achieve sodium balance. Renal inflammation is both the cause and the consequence of renal medullary ischemia, the hallmark of both initiation and progression of salt-dependent hypertension in rodents.

Low Birth Weight

Consequent to fetal undernutrition, low birth weight with reduced nephrogenesis increases the risk for development of adult salt-dependent hypertension. This association does not depend on shared genes, shared postnatal environment, or risk factors for adult hypertension. Hypertensive adults have fewer glomeruli per kidney but very few obsolescent glomeruli, suggesting that nephron dropout with decreased total filtration surface area is the cause and not the consequence of the hypertension. When low-birth-weight children are exposed to a fast-food diet, they are susceptible to rapid weight gain, leading to adolescent obesity and hypertension.

Genetic Contributions

Animal and human studies have implicated an important genetic contribution to salt-sensitive hypertension. Rats with inbred defects in the kidneys' ability to excrete sodium remain relatively normotensive on a sodium-restricted diet, but become severely hypertensive when fed a high-sodium diet—a model of salt-sensitive hypertension that can be cured by interstrain renal transplantation. A similar gene-environment interaction may explain why persons of sub-Saharan African ancestry remain normotensive on a sodium-restricted diet but are predisposed to the development of hypertension when they are exposed to a high-sodium diet. Ancestral gene analysis has not ascertained the molecular basis for salt-dependent human hypertension but has identified a common genetic predisposition in African-origin populations to all nondiabetic forms of CKD, including focal glomerulosclerosis, acquired immunodeficiency syndrome (AIDS), and hypertensive nephropathy. Sequence variations in the *APOL1* gene are strongly associated with African ancestry and confer a twofold to fourfold increased risk of end-stage renal disease, independent of blood pressure.³⁸ As the kidneys fail, blood pressure becomes increasingly salt-dependent.

Vascular Mechanisms

Alterations in the structure and function of small and large arteries are pivotal in the pathogenesis and progression of hypertension.

Endothelial Cell Dysfunction

The endothelial lining of blood vessels is critical to vascular health and constitutes a major defense against hypertension. Dysfunctional

Oxidative stress also contributes to endothelial cell vasodilator dysfunction in hypertension. Superoxide anion and other reactive oxygen species quench nitric oxide, thereby reducing its bioavailability.⁴¹ Several pathways produce superoxide in arteries: nicotinamide adenine dinucleotide phosphate (NADPH) oxidases, which are expressed in all vascular cell types and activated by circulating A II; nitric oxide synthase, which produces superoxide only when an important cofactor (tetrahydrobiopterin) is deficient, a process known as nitric oxide synthase uncoupling; xanthine oxidase, which produces uric acid; and mitochondria. Generation of reactive oxygen species by xanthine oxidase accounts for the association of hyperuricemia with endothelial dysfunction and hypertension. The xanthine oxidase inhibitor allopurinol can normalize blood pressure in

Activation of the renin-angiotensin-aldosterone system (RAAS) (see Fig. 22-4) is one of the most important mechanisms contributing to endothelial cell dysfunction, vascular remodeling, and hypertension

FIGURE 43-9 Vascular remodeling of small and large arteries in hypertension. Diagrams represent arteries in cross section showing the tunica adventitia, tunica media, and tunica intima. (Modified from Duprez DA: Role of renin-angiotensin-aldosterone system in vascular remodeling and inflammation: A clinical review. *J Hypertens* 24:983, 2006.)

FIGURE 43-10 The renin-angiotensin-aldosterone system. AT₁R = angiotensin receptor type 1; CNS = central nervous system.

(Fig. 43-10). Renin, a protease produced solely by the renal juxtaglomerular cells, cleaves angiotensinogen (renin substrate produced by the liver) to angiotensin I (A I), which is converted to A II by angiotensin-converting enzyme (ACE) (see Chapter 88). ACE is most abundant in the lungs but also is present in the heart and systemic vasculature (tissue ACE). Chymase, a serine protease in the heart and systemic arteries, provides an alternative pathway for conversion of A I to A II. The interaction of A II with G protein–coupled AT₁ receptors activates numerous cellular processes that contribute to

hypertension and accelerate hypertensive end-organ damage (see Fig. 43-10), including vasoconstriction, generation of reactive oxygen species, vascular inflammation, vascular and cardiac remodeling, and production of aldosterone, the principal mineralocorticoid. Increasing evidence shows that aldosterone, A II, and even renin and prorenin activate multiple signaling pathways that can damage vascular health and cause hypertension.

Aldosterone and Epithelial Sodium Channel Regulation

RAAS activation is a major homeostatic mechanism to counter hypovolemic hypotension (as with hemorrhage or salt and water deprivation). Interaction of aldosterone with cytosolic mineralocorticoid receptors in the renal collecting duct cells recruits sodium channels from the cytosol to the surface of the renal epithelium. The recruited epithelial sodium channels (ENaCs) increase sodium reabsorption, thereby reexpanding plasma volume. Conversely, modern high-salt diets should engender continual feedback inhibition of the RAAS. Suppression of serum aldosterone should trigger sequestration of ENaCs by endocytosis and increased renal sodium excretion, thereby shrinking plasma volume to protect against salt-sensitive hypertension.

Thus, in the setting of high dietary sodium and elevated blood pressure, the RAAS should be completely suppressed, and any degree of RAAS activity is inappropriate. In normotensive persons, the risk for development of hypertension increases with increasing levels of serum aldosterone that are well within the normal range. By stimulating mineralocorticoid receptors in the heart and kidney, circulating aldosterone may contribute to the development of cardiac and renal fibrosis in hypertension.⁴⁴ Aldosterone also may contribute to sympathetic overactivity by stimulating mineralocorticoid receptors in the brainstem.

Receptor-Mediated Actions of Angiotensin II

Two main angiotensin receptor types (AT) are known. AT₁ receptors are widely expressed in the vasculature, kidneys, adrenals, heart, liver, and brain. A I receptor activation explains most of the hypertensive actions of A II (see Fig. 43-10). Furthermore, enhanced AT₁-mediated signaling provides a central mechanistic explanation for the frequent coexistence of elevated blood pressure with insulin resistance and atherosclerosis and constitutes a major

therapeutic target for interruption of every step in cardiovascular disease progression, from vascular remodeling and formation of atherosclerotic plaque to stroke, MI, and death (Fig. 43-11).

By contrast, AT₂ receptors are distributed widely in the fetus, but in adults they localize only in the adrenal medulla, uterus, ovaries, vascular endothelium, and distinct brain regions. In rodents, AT₂ receptor activation opposes some of the deleterious effects of AT₁ receptors by promoting endothelium-dependent vasodilation by bradykinin and nitric oxide pathways. Animal studies have suggested

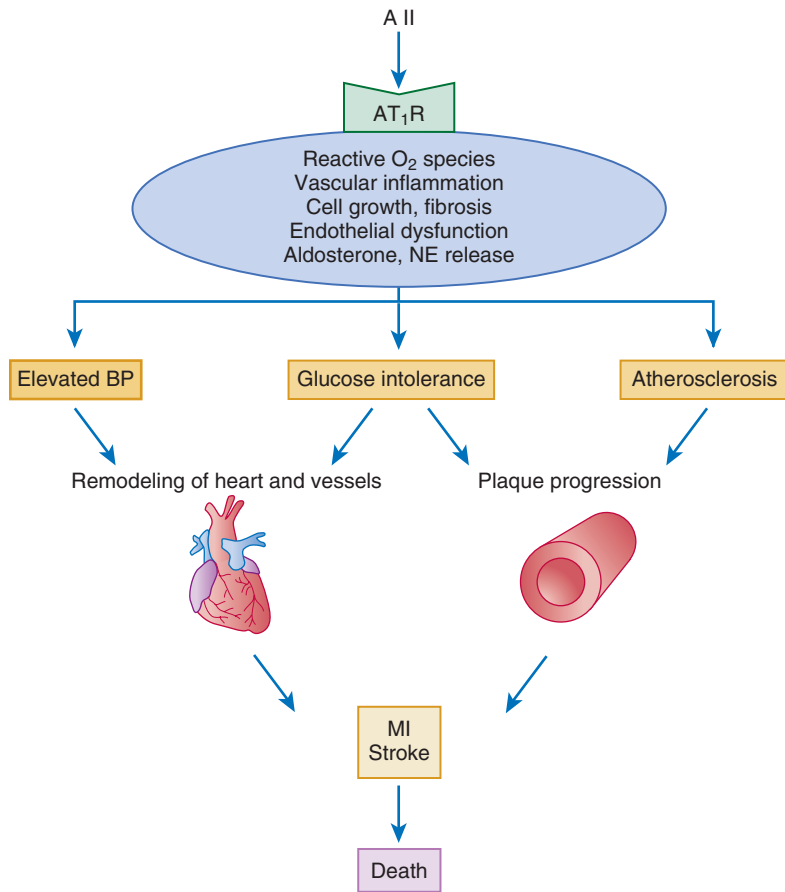

FIGURE 43-11 Schematic representation of the central role of angiotensin receptor type 1 (AT₁R)-mediated signaling in cardiovascular disease progression. BP = blood pressure; NE = norepinephrine.

that AT₂ receptors can be profibrotic, but their role in human hypertension remains speculative. The finding of several angiotensin metabolites also has added to the recognized complexity of the RAAS (Fig. e43-4).

Receptor-Mediated Actions of Renin and Prorenin

Traditionally, prorenin was considered the inactive precursor of renin, an enzyme that generates A I by enzymatic cleavage of angiotensinogen. This concept is rapidly evolving as newer studies implicate prorenin and renin as direct cardiac and renal toxins. Prorenin is inactive because a 43-amino acid hinge is closed and prevents it from binding to angiotensinogen. The kidneys convert inactive prorenin to active renin by enzymatic cleavage of this inhibitory hinge region. When circulating prorenin binds to a newly discovered (pro)renin receptor in the heart and kidneys, the hinge is opened (but not cleaved), and this nonenzymatic process fully activates prorenin (Fig. e43-5). Activation of the (pro)renin receptor increases TGF- β production, leading to collagen deposition and fibrosis. This receptor-mediated process does not depend on A II generation, ACE inhibitors, or angiotensin receptor blockers (ARBs). Although these are excellent antihypertensive agents (see Chapter 44), they trigger large reactive increases in prorenin and renin production that may counter some of the cardiovascular protection afforded by reduced AT₁ receptor activation. The reactive increases are even greater with the direct renin inhibitor aliskiren, which reduces renin's ability to cleave angiotensinogen and to generate A I but nevertheless does not inhibit profibrotic signaling by the (pro)renin receptor.⁴⁵ Because prorenin blood levels normally exceed those of renin 100-fold, (pro)renin receptor activation may be an important factor in human hypertension.

Vascular Inflammatory Cells and Hypertension

Macrophages and T cells accumulate and promote inflammation in the central nervous system, perivascular fat, heart, and kidneys of mice with experimental hypertension, particularly that caused by infusion of A II.⁴⁶ Mice lacking T cells or macrophages are resistant to A II-induced hypertension (Fig. 43-12). Clinical studies are needed to translate this rapidly growing area of basic research to the pathogenesis and progression of human hypertension and to identify new drug targets.

PATHOGENESIS OF HYPERTENSIVE HEART DISEASE

Hypertension is a major risk factor not only for CAD but also for left ventricular hypertrophy (LVH) and heart failure.

Pressure Overload Hypertrophy

In hypertensive patients, LVH powerfully and independently predicts morbidity and mortality, predisposing them to heart failure, ventricular tachyarrhythmia, ischemic stroke, atrial fibrillation, and embolic stroke. Major advances have increased our understanding of the molecular signal transduction pathways underlying pressure overload cardiomyocyte hypertrophy.⁴⁷ Moreover, the structural abnormalities in the hypertensive heart extend beyond myocyte hypertrophy; they also include medial hypertrophy of the intramyocardial coronary arteries and collagen deposition, leading to cardiac fibrosis.⁴⁸ These changes result from pressure overload and the neurohormonal activation that contributes to hypertension. In animal models, A II, aldosterone, norepinephrine, and prorenin accelerate pressure overload cardiomyocyte hypertrophy and promote cardiac fibrosis, the hallmarks of pathologic LVH (in contrast with the physiologic hypertrophy of exercise training, which involves less fibrosis).

Impaired Coronary Vasodilator Reserve

The hypertrophied hypertensive heart has normal resting coronary blood flow, but vasodilator reserve becomes impaired when myocyte mass outstrips the blood supply. Even in the absence of atherosclerosis, the hypertensive heart has blunted or absent coronary vasodilator reserve, leading to subendocardial ischemia under conditions of increased myocardial oxygen demand. The combination of subendocardial ischemia and cardiac fibrosis impairs diastolic relaxation, leading to exertional dyspnea and heart failure with preserved systolic function.

Heart Failure

Before the advent of effective drug therapy for hypertension in the late 1950s, heart failure caused most deaths from hypertension (see Chapters 25 and 27). Better management has substantially reduced hypertension-related deaths from heart failure and significantly delayed its onset, but hypertension remains the most common cause of heart failure with preserved systolic function. In addition, hypertension indirectly leads to systolic heart failure as a major risk factor for MI. Whether mild or moderate hypertension without MI leads to systolic heart failure is unclear.⁴⁸

DIAGNOSIS AND INITIAL EVALUATION OF HYPERTENSION

Hypertension has been termed the silent killer, an asymptomatic chronic disorder that, undetected and untreated, silently damages

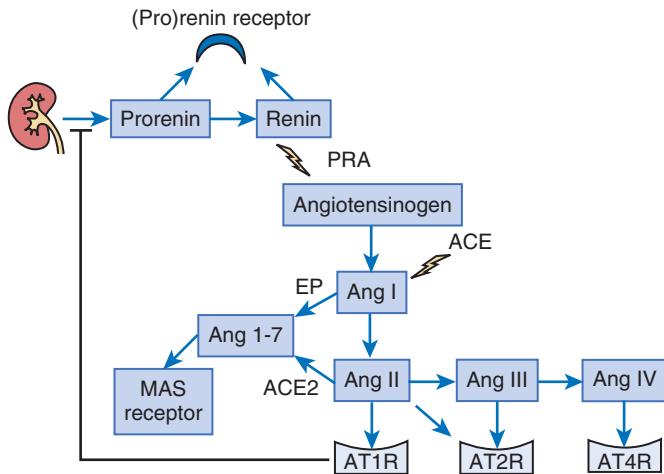

FIGURE e43-4 Increasing complexity in understanding of the renin-angiotensin system. The A II metabolite Ang 1-7 interacts with a specific G protein-coupled MAS receptor and generally opposes the vasoconstrictor and proliferative actions of Ang II. FIGURE 43-12 Proposed paradigm for inflammation and immune cell activation in hypertension. Stimuli including angiotensin II (A II), salt, and chronic stress act on the central nervous system and increase sympathetic outflow. The circumventricular organs (CVO), including the subfornical organ (SFO), the median preoptic eminence (MPO, orange structure), organum vasculosum lateral terminalis (OVLT, yellow structure), and the area postrema (AP) have a poorly formed blood-brain barrier and are responsive to circulating A II and sodium. These stimuli increase production of reactive oxygen species (ROS) in the CVO, which provide input into hypothalamic centers including the paraventricular nucleus (PVN). Microglial cells are activated in this process and increase input into brainstem centers, including the ventral lateral medulla (VLM) and the nucleus tractus solitarius (NTS). These increase sympathetic outflow, which causes a modest elevation in blood pressure to levels compatible with prehypertension. Sympathetic activation also increases renal production of interleukin 6 (IL-6) and acts on T cell adrenergic receptors to modify their polarization. The elevations of pressure, direct actions, and A II and catecholamines activate ROS production in the kidney and vasculature, increasing chemokine production and adhesion molecule expression. Neoantigens (nAg) are formed from endogenous proteins in the kidney and vasculature, which are presented by dendritic cells to T cells. Activated T cells interact with monocytes/macrophages, promoting macrophage transformation, and these leukocytes accumulate in the kidney. IL-6 and transforming growth factor-beta (TGF-β), produced in these organs, help direct T cell interleukin 17 (IL-17) production. IL-17 and other cytokines produced by these cells promote ROS production in the vascular smooth muscle and kidney, leading to vasoconstriction, sodium retention, and ultimately severe hypertension. AV3V = anteroventral third ventricle. (From Harrison DG, Marvar PJ, Titze JM: Vascular inflammatory cells in hypertension. *Front Physiol* 3:128, 2012.)

the blood vessels, heart, brain, and kidneys. It may not be entirely asymptomatic, however; in double-blind placebo-controlled trials, patients' quality of life ratings often improve with successful drug treatment of hypertension. Control of hypertension can lead to clinical improvement in patients with exertional dyspnea caused by diastolic dysfunction, nocturia caused by resetting of pressure-natriuresis, and possibly even erectile dysfunction caused by endothelial dysfunction.

Initial Evaluation of the Hypertensive Patient

The initial evaluation for hypertension should accomplish three goals: accurate measurement of blood pressure; assessment of the patient's overall cardiovascular risk; and detection of secondary (i.e., identifiable and potentially curable) forms of hypertension.

Measurement of Blood Pressure Staging of Office Blood Pressure

The 2003 guidelines of the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7),⁸ staged blood pressure as normal, prehypertension, or hypertension by the average of two or more readings taken at two or more office visits (Table 43-1). Such office-based measurements, however, often overestimate blood pressure, as explained further on.

Measurement Technique

In the office, blood pressure should be measured at least twice after 5 minutes of rest, with the patient seated in a chair, the back supported, and the arm bare and at heart level (see Chapter 11). A large adult-size cuff should be used to measure blood pressure in overweight adults, in whom use of a standard-size cuff can spuriously elevate readings. Tobacco and caffeine should be avoided for at least 30 minutes. Blood pressure should be measured in both arms and after 5 minutes of standing, the latter to exclude a significant postural fall in blood pressure, particularly in older persons and in those with diabetes or other conditions (e.g., Parkinson's disease) that predispose to autonomic insufficiency.

The 2011 guidelines from the National Institute for Health and Clinical Excellence in the United Kingdom⁴⁹ recommend the following: (1) If blood pressure measured in the clinic is 140/90 mm Hg or higher, take a second measurement during the visit; (2) if the second measurement is substantially different from the first, take a third measurement; (3) record the lower of the last two measurements as the clinic blood pressure; (4) if the clinic blood pressure is 140/90 mm Hg or higher or there is evidence of hypertensive target organ disease, home or ambulatory blood pressure monitoring should be recommended to confirm the diagnosis of hypertension.

Home and Ambulatory Monitoring

An individual patient's blood pressure varies widely throughout a 24-hour period and is therefore impossible to characterize accurately, except by repeated measurements under various conditions (Fig. e43-6).

Out-of-office readings provide a clear picture of usual blood pressure for accurate diagnosis and management. These readings predict cardiovascular events better than office readings do, and they overcome many of the pitfalls of office measurement, including physician error and alerting (i.e., "white coat") reactions. Home blood pressure monitoring also improves medication adherence by actively involving patients in their own medical care.

TABLE 43-1 Staging of Hypertension for Office Blood Pressure Determination*

HYPERTENSION STAGE	SYSTOLIC PRESSURE (mm Hg)	DIASTOLIC PRESSURE (mm Hg)
Normal	<120	<80
Prehypertension	120-139	80-89
Stage 1 hypertension	140-159	90-99
Stage 2 hypertension	≥160	≥100

*Calculation of seated blood pressure is based on the mean of two or more readings on two separate office visits.

From Chobanian AV, Bakris GL, Black HR, et al: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: the JNC 7 report. *JAMA* 289:2560, 2003.

FIGURE e43-6 Twenty-four-hour ambulatory blood pressure (BP) monitor tracings in two different patients. **Left**, Optimal blood pressure in a healthy 37-year-old woman. Note the normal variability in blood pressure, the nocturnal dip in blood pressure during sleep, and the sharp increase in blood pressure on awakening. **Right**, Pronounced white coat effect in an 80-year-old woman referred for evaluation of medically refractory hypertension. Documentation of the white coat effect prevented overtreatment of the patient's isolated systolic hypertension. (**Left**, Courtesy Dr. Ronald G. Victor, Heart Institute/Hypertension Center, Cedars-Sinai Medical Center, Los Angeles. **Right**, Provided by Dr. Wanpen Vongpatanasin, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas.)

For these reasons, position papers on home blood pressure monitoring from both the United States and Europe make the following recommendations: Home blood pressure monitoring should become a routine part of the clinical management of patients with known or suspected hypertension, the same way in which home blood glucose monitoring is essential to the management of diabetes; two readings should be taken in the morning and at night for at least 4 consecutive days (preferably 7 days); the first day's readings should be excluded as being falsely elevated, and all other readings be averaged to make clinical decisions; and hypertension should be diagnosed when the average home blood pressure is 135/85 mm Hg or higher.⁴⁹

A validated electronic oscillometric monitor with an arm cuff should be chosen from the Dabl educational website (dableducational.org). Each patient's monitor needs to be checked in the office for accuracy and cuff size. Patients need to be taught correct measurement technique and how to avoid reporting bias. Wrist monitors are inaccurate and are therefore not recommended. The oscillometric method may not work well in patients with atrial fibrillation or frequent extrasystoles. Some patients become obsessive about taking their blood pressure and should be advised to stop self-measurement altogether.

Ambulatory monitoring provides automated measurements of blood pressure during a 24-hour period while patients are engaged in their usual activities, including sleep. Prospective outcome studies in both treated and untreated patients have shown that ambulatory blood pressure measurement predicts fatal and nonfatal MI and stroke better than standard office measurement does⁵⁰ (Fig. 43-13). Recommended normal values include an average daytime pressure below 135/85 mm Hg, nighttime pressure below 120/70 mm Hg, and 24-hour pressure below 130/80 mm Hg. Hypertension is diagnosed if the average daytime blood pressure is 135/85 mm Hg or higher or the average 24-hour blood pressure is greater than 130/80 mm Hg. At least two measurements per hour should be taken during the patient's waking hours, and the average value of at least 14 measurements during that time confirms the diagnosis of hypertension.⁴⁹ Whether nocturnal dipping status adds independent prognostic information remains controversial.

White Coat Hypertension

Some patients with elevated office blood pressures have normal home or ambulatory blood pressures. If the daytime blood pressure

FIGURE 43-13 Superiority of ambulatory over office blood pressure (BP) measurement as a measure of cardiovascular risk. Shown is the adjusted 5-year risk of cardiovascular death (number of deaths per 100 subjects) in the study cohort of 5292 patients for office blood pressure and ambulatory blood pressure. (From Dolan E, Santon A, Thijs L, et al: Superiority of ambulatory over clinic BP measurement in predicting mortality: The Dublin outcome study. *Hypertension* 46:156, 2005.)

is below 135/85 mm Hg and there is no target organ damage despite consistently elevated office readings, the patient has “office-only” or white coat hypertension, caused by a transient adrenergic response to the measurement of blood pressure only in the physician's office. White coat hypertension is particularly common in older patients. The prognostic importance of white coat hypertension depends on treatment status. In untreated patients, the long-term cardiovascular risk in older persons with white coat hypertension is indistinguishable from that in normotensive persons. But treated patients with high office readings but normal ambulatory readings are at greater cardiovascular risk than untreated normotensive patients.⁵¹

Many patients do not have pure white coat hypertension but rather exhibit “white coat aggravation,” a white coat reaction superimposed on a milder level of out-of-office hypertension that nevertheless needs treatment (see Fig. e43-6). Currently, Medicare reimburses ambulatory blood pressure monitoring (Current Procedural Terminology [CPT] code 93784) for suspected white coat hypertension if the following criteria are met: office blood pressure above 140/90 mm Hg on at least three separate office visits, with two measurements made at each visit; at least two out-of-office blood pressure readings below 140/90 mm Hg; and no evidence of target organ damage (International Statistical Classification of Diseases and Related Health Problems [ICD] code 796.2: elevated blood pressure without a diagnosis of hypertension). The indications for ambulatory monitoring should be expanded. In up to 30% of treated patients with persistently elevated office blood pressure, for example, ambulatory monitoring documents adequate or excessive control of hypertension, a finding that can limit overtreatment.

Automated office blood pressure measurement may be an easier approach to detecting white coat hypertension.⁵² With the patient in a quiet room with no medical personnel, six readings are taken in rapid succession with an oscillometric blood pressure monitor. If the average of the last five readings is less than 135/85 mm Hg, the patient is assumed to have normal blood pressure; if the average is 135/85 mm Hg or higher, the patient is assumed to have hypertension.

Masked Hypertension

Another example of the importance of ambulatory or home monitoring is in patients in whom office readings underestimate out-of-office blood pressure, presumably because of sympathetic overactivity in daily life caused by job or home stress, tobacco abuse, or other adrenergic stimulation that dissipates when they come to the office (Fig. 43-14). Such documentation prevents undertreatment of this

FIGURE 43-14 A 24-hour ambulatory blood pressure (BP) recording in a patient with apparently normal office blood pressure but with masked hypertension and nocturnal hypertension. (Courtesy Dr. R.G. Victor, Cedars-Sinai Medical Center, Los Angeles.)

masked hypertension, which can affect more than 10% of patients and clearly increases cardiovascular risk, despite normal office blood pressure readings.

Other Uses of Ambulatory Monitoring

Ambulatory monitoring is the only way to detect hypertension during sleep (see Fig. 43-14). Blood pressure normally dips during sleep and increases sharply when a person awakens and becomes active (see Fig. e43-6). Nocturnal hypertension increases the aggregate hemodynamic load on the cardiovascular system and predicts cardiovascular outcomes better than either daytime ambulatory blood pressure or standard office measurements (see Fig. 43-13).⁵⁰ Nocturnal hypertension is particularly common among patients with CKD, presumably because of increased cardiac output (centralization of an expanded plasma volume while supine) and increased systemic vascular resistance (failure of sympathetic vasoconstrictor drive to suppress normally during sleep because of persistent activation of an excitatory reflex in the diseased kidneys). In addition, ambulatory blood pressure monitoring is particularly useful in the diagnosis of baroreflex impairment.

Cardiovascular Risk Stratification

In hypertensive persons, cardiovascular risk increases sharply with blood pressure stage, but this is not the only factor to consider (see Chapter 42). The gradient between increasing levels of blood pressure and cardiovascular risk becomes progressively steeper as additional risk factors accumulate. Cardiovascular risk also increases dramatically with hypertensive target organ damage and with additional cardiovascular risk factors often present in patients with hypertension or prehypertension⁵³ (Table 43-2). In particular, more than 75% of hypertensive patients meet current criteria for initiation of lipid-lowering medication (low-density lipoprotein [LDL] cholesterol level > 130 mg/dL), and 25% have diabetes.⁵⁴ Thus the minimum laboratory testing required for the initial evaluation of hypertension includes determination of blood electrolyte values, fasting glucose concentration, and serum creatinine level with calculated glomerular

filtration rate (GFR); fasting lipid panel; hematocrit; spot urinalysis, including urine albumin-to-creatinine ratio; and resting 12-lead electrocardiogram.

The patient's global cardiovascular risk should be estimated from standard websites (e.g., my.americanheart.org/cvriskscalculator; <http://www.reynoldsriskscore.org/>; http://www.kardioblab.ch/MONICA-PROCAM3_RA1.html). Decisions regarding treatment thresholds and treatment targets, however, still depend largely on specific blood pressure cutoffs rather than on an individual patient's actual level of global cardiovascular risk. Higher-risk hypertensive patients are more likely to be treated with blood pressure medication but less likely to have their office blood pressure controlled to below 140/90 mm Hg.⁵⁵

Emerging Methods to Improve Cardiovascular Risk Stratification in Hypertension

BLOOD PRESSURE VARIABILITY. In addition to average blood pressure, day-to-day (office visit-to-visit) variability in blood pressure has been proposed as an independent predictor of cardiovascular risk,⁵⁶ but the evidence is conflicting.⁵⁷

HEART RATE VARIABILITY. Frequency analysis of heart rate provides an indirect assessment of sympatho-vagal control of sinus node function. Whether heart rate variability provides independent prognostic information in hypertension remains controversial.

NONINVASIVE MEASUREMENT OF CENTRAL AORTIC PRESSURE BY PULSE TONOMOMETRY. The central aortic pressure waveform is the sum of the pressure wave generated by the left ventricle and reflected waves from the peripheral circulation. When the large conduit arteries are healthy and compliant, the reflected wave merges with the incident wave during diastole, which enhances coronary blood flow. But when the conduit arteries become stiff (as in ISH), pulse wave velocity increases such that the reflected and incident waves merge in systole, thereby augmenting systolic rather than diastolic pressure—which increases left ventricular afterload and reduces diastolic coronary flow. Sphygmocor (AtCor Medical, Houston) is a commercial device that uses brachial artery blood pressure and a generalized transfer function (proprietary software) to convert the radial waveform—measured by applanation tonography—to a derived central aortic blood pressure waveform (see Fig. e43-1). This device has received FDA approval for clinical use in (CPT code 93784). Pulse tonometry provides two principal measures of aortic stiffness that typically are increases in hypertension: pulse wave velocity and augmentation index.^{58,59}

ERECTILE DYSFUNCTION. Self-reported erectile dysfunction occurs in more than half of men with hypertension and independently predicts fatal and nonfatal cardiovascular events.⁶⁰

Evaluation of Target Organ Disease

Traditionally, the complications of hypertension are viewed as hypertensive (caused by the increased level of blood pressure per se) or atherosclerotic (caused by concomitant atherosclerosis), with blood pressure elevation playing a variable role. This view is oversimplified, however, because both types of complications frequently coexist, as exemplified by hypertensive retinopathy (Fig. e43-7)⁶¹ or hypertensive heart disease.

Hypertensive Heart Disease

Hypertension may contribute to CAD more than is commonly realized because hypertensive persons have more silent ischemia and unrecognized MIs, and patients with acute MI often have preexisting hypertension that evaded detection or treatment. Assessment of blood pressure is inaccurate during an acute coronary syndrome because of pain-induced blood pressure rise, or dysautonomia or pump failure that decreases blood pressure. Preexisting hypertension increases the case-fatality rate associated with an acute MI and substantially increases the risk of hemorrhagic stroke during thrombolytic therapy, especially when systolic blood pressure exceeds 175 mm Hg.

On the electrocardiogram, LVH with strain is a serious harbinger of new-onset heart failure and heart failure death.⁶² Echocardiography detects LVH more sensitively than electrocardiography does.

TABLE 43-2 Factors Influencing Prognosis in Patients with Hypertension

Risk Factors for Cardiovascular Disease
Increased systolic and diastolic blood pressure levels
Increased pulse pressure (in the elderly)
Age: men, > 55 years; women, > 65 years
Smoking
Dyslipidemia (LDL cholesterol > 115 mg/dL)
Impaired fasting glucose (102-125 mg/dL) or abnormal glucose tolerance test result
Family history of premature cardiovascular disease
Abdominal obesity
Diabetes mellitus
Subclinical Target Organ Damage
Left ventricular hypertrophy
Carotid wall thickening or plaque
Low estimated glomerular filtration rate ≤ 60 mL/min/1.73 m ²
Microalbuminuria
Ankle-brachial index < 0.9
Established Target Organ Damage
Cerebrovascular disease: ischemic stroke, cerebral hemorrhage, transient ischemic attack
Heart disease: myocardial infarction, angina, coronary revascularization, heart failure
Renal disease: diabetic nephropathy, renal impairment
Peripheral arterial disease
Advanced retinopathy: hemorrhages or exudates, papilledema

Modified from Mancia G, De Backer G, Dominiczak A, et al: 2007 guidelines for the management of arterial hypertension: the Task Force for the Management of Arterial Hypertension of the European Society of Hypertension (ESH) and of the European Society of Cardiology (ESC). *Eur Heart J* 28:1462, 2007.

FIGURE e43-7 Retinal photographs showing the stages of hypertension retinopathy. **A**, Mild diffuse arteriolar narrowing. **B**, Arterial-venous nicking. **C**, Hemorrhages and exudates. **D**, Papilledema. (From Grosso A, Veglio F, Porta M, et al: Hypertensive retinopathy revisited: some answers, more questions. *Br J Ophthalmol* 89:1646, 2005.)

Whereas electrocardiographic LVH is present in 5% to 10% of hypertensive persons, echocardiographic LVH is present in nearly 30% of unselected hypertensive adults and in up to 90% of patients with severe uncontrolled hypertension. Cardiac magnetic resonance (CMR) is even more sensitive, detecting LVH in 28% of whites with hypertension but in 62% of blacks with hypertension.⁶³

Large-Vessel Disease

Hypertension also constitutes a major risk factor for, and is present in, an overwhelming majority of patients with aortic dissection (distal more than proximal dissection), abdominal aortic aneurysm, and peripheral arterial disease (see Chapters 57 and 58). One-time abdominal ultrasound screening for abdominal aortic aneurysm is recommended after the age of 65 years in smokers and in those with severe systolic hypertension, and it should be performed if aortic pulsations are detected below the umbilicus, because most abdominal aortic aneurysms occur below the origin of the renal arteries. Hypertension occurs in 50% of patients with Takayasu arteritis (see Chapter 84).

Cerebrovascular Disease

Hypertension is a major risk factor for stroke and dementia, often the two most dreaded complications of aging. Hypertension accounts for 50% of strokes (see Chapter 59). In hypertensive persons, 80% of strokes are ischemic (thrombotic or embolic) and 20% are hemorrhagic. The onset of ischemic stroke markedly increases on awakening, corresponding to the morning surge in blood pressure. Hypertensive patients with asymptomatic carotid bruits should undergo Doppler ultrasonography. Older patients with ISH have a particular risk of stroke. In middle-aged and elderly hypertensive patients, remarkably common asymptomatic cerebral white matter lesions on magnetic resonance imaging (MRI) likely accelerate the brain atrophy and vascular dementia that occur with aging.

Chronic Kidney Disease

Hypertension follows only diabetes as a risk factor for CKD (see Chapter 88). Traditionally, the typical pathologic change of small, scarred kidneys (termed hypertensive nephrosclerosis), likely resulting from chronic exposure of the renal parenchyma to excessive pressure and flow, is the most common cause of end-stage renal disease among blacks. But recent genetic analysis of the non-diabetic participants of the African American Study of Kidney Disease (AASK) indicates that many cases of presumed hypertensive nephrosclerosis in black patients are genetically determined by a risk allele on chromosome 22—apolipoprotein L1 (*APOLI*) gene variants which are common among blacks and infrequent among whites.³⁸

Quantitative estimates of urinary albumin excretion and GFR (the latter from www.kdoqi.org) should be obtained from a spot urine collection. Microalbuminuria (defined as a urine albumin-to-urine creatinine ratio of 30 to 300 mg/g) is a sensitive early marker of kidney damage and a powerful independent predictor of cardiovascular complications from hypertension, presumably because it reflects systemic vascular disease (see also Chapter 88). In patients

with hypertension, renal damage dramatically increases the risk of a cardiovascular event. Most patients with hypertension-associated CKD die of heart attack or stroke before renal function deteriorates sufficiently to require chronic hemodialysis.

Identifiable (Secondary) Forms of Hypertension

The third goal of the initial evaluation is to detect identifiable causes of hypertension, thereby offering the possibility of cure to some patients, particularly those with severe or refractory hypertension (Table 43-3).

Renal Parenchymal Disease

Renal parenchymal disease is the most common cause of secondary hypertension, responsible for 2% to 5% of cases (see Chapter 88). As chronic glomerulonephritis has become less common, diabetes and hypertension are the most common risk factors for CKD. The prevalence of chronic renal disease, defined by a reduction in the GFR to less than 60 mL/min/1.73 m² or persistent albuminuria of more than 300 mg/day, affects approximately 11% (19.2 million) of the adult U.S. population.

As previously noted, microalbuminuria of 30 to 300 mg/day relates closely to target organ damage and should be determined in every new hypertensive patient by testing of a single voided urine specimen. Measurement of the serum creatinine level by itself is an inadequate screening test for significant renal damage, particularly in elderly patients. Creatinine clearance therefore should be calculated with the Cockcroft-Gault equation or the Modification of Diet in Renal Disease (MDRD) equation, taking age, sex, and body weight into account. But the MDRD equation does not account for other factors that affect creatinine generation by muscle, such as diet and physical conditioning. Measurement of serum cystatin C, an endogenous 13-kDa protein filtered by the glomeruli and reabsorbed and metabolized by the proximal tubular epithelium, with very little being excreted in the urine, has promise as a replacement for serum creatinine determination because it is less affected by muscle mass.⁶⁴ Once renal disease begins, it usually progresses, in keeping with the concept that a loss of filtration surface leads to both glomerular and systemic hypertension, which engenders more glomerular sclerosis, setting up a cycle of progressive disease. Identifying renal damage early therefore is critical, because removal of causal or aggravating factors can prevent the otherwise inexorable progress of renal damage. These factors include obstruction of the urinary tract, depletion of effective circulating volume, nephrotoxic agents, and most important, uncontrolled hypertension.

Acute Renal Diseases

Hypertension may appear with any sudden, severe insult to the kidneys that markedly impairs excretion of salt and water, which leads to volume expansion, or that reduces renal blood flow (e.g., sudden bilateral renal ischemia because of cholesterol emboli), or which activates the RAAS (e.g., bilateral ureteral obstruction). Reversal of hypertension has been particularly striking in men with high-pressure chronic retention of urine, who may exhibit renal failure and

TABLE 43-3 Overall Guide to Workup for Identifiable Causes of Hypertension

DIAGNOSIS	DIAGNOSTIC PROCEDURE(S)	
	Initial	Additional
Chronic renal disease	Urinalysis, serum creatinine, renal sonography	Isotopic renography, renal biopsy
Renovascular disease	Renal sonography (atrophic kidney)	Magnetic resonance or computed tomography (CT) angiography, Duplex Doppler sonography, digital subtraction renal angiography
Coarctation	Blood pressure in legs	Echocardiography, magnetic resonance imaging, aortography
Primary aldosteronism	Plasma renin, serum aldosterone	Salt loading, adrenal vein sampling
Cushing syndrome	1-mg dexamethasone suppression test	Urinary cortisol after variable doses of dexamethasone, adrenal CT, scintiscans
Pheochromocytoma	Plasma-free metanephrines	24-hour urinary metanephrines and catecholamines, adrenal CT

severe hypertension, both of which may decrease in severity or degree after relief of the obstruction. Hypertension can be the presenting sign of vasculitis involving the kidney.

Two commonly used classes of drugs—nonsteroidal anti-inflammatory drugs (NSAIDs) and inhibitors of the renin-angiotensin system—may suddenly worsen renal function in patients with preexisting renal diseases. NSAIDs block the synthesis of prostaglandins, which act as vasodilators within the kidney. Renin-angiotensin inhibitors (both ACE inhibitors and ARBs) may precipitate acute renal failure in patients with bilateral renovascular disease whose renal perfusion depends on high levels of Ang II.

Chronic Renal Diseases

All chronic renal diseases associate with a higher prevalence of hypertension, and hypertension accelerates the progression of renal damage regardless of the underlying cause of the renal disease. In patients with CKD, the control of hypertension slows the progression to end-stage renal disease, but uncertainty remains regarding the blood pressure goal of antihypertensive therapy in these patients. The mislabeling of APOL1 nephropathy as hypertensive nephrosclerosis may explain why renal function continued to decline 5 years after completion of the AASK trial, despite achievement of a blood pressure of 133/78 mm Hg on an ACE inhibitor–based regimen.³⁸

With whatever drugs are chosen to treat hypertension with CKD, and particularly with ACE inhibitors and ARBs, caution is needed to avoid lowering blood pressure too rapidly and in the presence of previously unrecognized bilateral renovascular disease, found in some patients with progressive renal damage. Of note, however, a modest increase in the serum creatinine level, averaging 30% above baseline, predicts better preservation of renal function—presumably reflecting a successful reduction in intraglomerular pressure. Patients with CKD commonly have nocturnal hypertension, detectable by 24-hour ambulatory blood pressure monitoring (see Figs. 43-13 and 43-14).⁶⁵

Patients with diabetic nephropathy (see Chapters 61 and 88) show particular protection against progressive renal damage by reduction of elevated blood pressure with an ARB-based or ACE inhibitor–based regimen. The results of the Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints (ALTITUDE) show that addition of the direct renin inhibitor aliskiren to standard RAAS blockade with either an ACE inhibitor or an ARB in high-risk patients with type 2 diabetes did not improve cardiovascular or renal outcomes as compared with standard RAAS blockade alone, but produced higher rates of adverse events, especially hyperkalemia and hypotension.⁶⁶ Based on these results, the FDA issued a black box warning that aliskiren is contraindicated in patients with type 2 diabetes being treated with an ACE inhibitor or ARB and should be avoided in nondiabetic patients being treated with an ACE inhibitor or ARB for nondiabetic CKD.

Most patients with CKD require at least two more drugs in addition to an ACE inhibitor or ARB—typically, a loop diuretic and a calcium channel blocker—to control their hypertension.

Hemodialysis Patients

In patients on dialysis, hypertension is a risk factor for mortality. Beyond the primary influence of excess fluid volume, the accumulation of endogenous inhibitors of nitric oxide synthase and sympathetic overactivity can accentuate hypertension. With neither the vasoconstrictor effects of renal renin nor the vasodepressor actions of various renal hormones, blood pressure may be particularly labile and sensitive to changes in fluid volume. In patients undergoing maintenance hemodialysis every 48 hours, elevated blood pressures tend to fall progressively after dialysis is completed, remain depressed during the first 24 hours, and rise again during the second day as a result of excessive fluid retention. Gradually achieving and maintaining dry weight, however, as with 8-hour nocturnal hemodialysis, can greatly improve blood pressure control.

Renal Transplantation

Although successful renal transplantation may cure primary hypertension, various problems can result, with approximately 50% of

recipients becoming hypertensive within 1 year. These problems include stenosis of the renal artery at the site of anastomosis, rejection reactions, high doses of glucocorticoids and cyclosporine or tacrolimus, and excess renin derived from the retained diseased kidneys. ACE inhibitor or ARB therapy may obviate the need to remove the native diseased kidneys to relieve hypertension caused by their persistent secretion of renin. The source of the donor kidney may also play a role in the subsequent development of hypertension in the recipient. Hypertension occurs more frequently when donors have a family history of hypertension or when donors have died of subarachnoid hemorrhage and probably had high blood pressure.

Renovascular Hypertension

The prevalence of proven renovascular hypertension in the overall hypertensive population is unknown, but significant renal artery stenosis occurs in 14% of hypertensive patients undergoing coronary angiography followed by renal angiography. Such “drive-by” renal angiography is discouraged. Renal artery stenosis is rather easy to find but difficult to prove as the cause of reversible hypertension. Moreover, the risks of revascularization often outweigh the benefits (see Chapter 60).^{67,68,68b}

Screening should focus on hypertensive patients who have multiple features known to associate with renovascular hypertension. The greater the number of clues, the more extensive the search should be (Table 43-4).

CLASSIFICATION. In adults, the two major types of renovascular disease tend to appear at different times and to affect men and women differently. Atherosclerotic disease affecting mainly the proximal third of the main renal artery occurs mostly in older patients with atherosclerotic risk factors. Fibromuscular disease (FMD) involving mainly the distal two thirds and branches of the renal arteries appears most commonly in women between 20 and 60 years of age. FMD typically affects the media but also can involve the intima and adventitia; bilateral carotid FMD may accompany renal FMD.⁶⁹

Other intrinsic and extrinsic causes of renovascular hypertension include cholesterol emboli in the renal artery or compression of this vessel by nearby tumors. Most renovascular hypertension develops from partial obstruction of one main renal artery, but only a branch need be involved; segmental disease exists in approximately 10% of cases. On the other hand, if apparent complete occlusion of the renal artery develops slowly, enough collateral flow will become available to preserve the viability of the kidney. Such seemingly nonfunctioning kidneys may secrete renin and cause hypertension. Totally

TABLE 43-4 Clinical Clues to Presence of Renovascular Hypertension

History
Onset of hypertension before 30 years or after 50 years of age
Abrupt onset of hypertension
Severe or resistant hypertension
Symptoms of atherosclerotic disease elsewhere
Negative family history of hypertension
Smoker
Worsening renal function after renin-angiotensin inhibition
Recurrent “flash” pulmonary edema
Physical Examination Findings
Abdominal bruits
Other bruits
Advanced fundal changes
Laboratory Findings
Secondary aldosteronism
Higher plasma renin level
Low serum potassium level
Low serum sodium level
Proteinuria, usually moderate
Elevated serum creatinine level
Unilateral small (atrophic) kidney size by ultrasound examination

occluded vessels can sometimes be repaired, resulting in return of renal function and relief of hypertension. Renovascular stenosis is often bilateral, although usually one side predominates. Bilateral disease should be suspected in those with renal insufficiency, particularly if rapidly progressive oliguric renal failure develops without evidence of obstructive uropathy, and even more so if it develops after the start of ACE inhibitor or ARB therapy.

MECHANISMS. The sequence of changes in patients with renovascular hypertension starts with the release of increased amounts of renin when sufficient ischemia is induced to diminish pulse pressure against the juxtaglomerular cells in the renal afferent arterioles. A 50% reduction in renal perfusion pressure leads to an immediate and persistent increase in renin secretion from the ischemic kidney, along with suppressed secretion from the contralateral one. With time, an expanded body fluid volume causes renin levels to fall, but not to the low level expected from the elevated blood pressure.

DIAGNOSIS. The clinical features listed in Table 43-4, found in perhaps 5% to 10% of all hypertensive persons, indicate the need for a screening test for renovascular hypertension. A positive screening test result or very strong clinical features call for more definitive confirmatory tests. The initial diagnostic study in most patients should be noninvasive, and abnormal results should lead to a study of renal perfusion to confirm that any renovascular lesion is pathogenic and to guide consideration for revascularization.

All screening tests have limitations. Considerable asymmetry of renal blood flow, 25% or more, was found in 148 hypertensive patients whose renal arteries were patent on previous angiography. Such normal asymmetry likely accounts for the low sensitivity and specificity of captopril-enhanced renal scans. Similarly, renal duplex sonography for the detection of hemodynamically significant renovascular disease has a sensitivity of only approximately 50%. The accuracy of ultrasonography is operator-dependent, but the outcome of revascularization is associated with the use of a resistance index to assess flow in renal arteries. Patients with high resistance index values (above 80), reflecting marked intrarenal vascular disease, had generally poor outcomes. Those with lower values had generally good outcomes.

During the past decade, contrast-enhanced computed tomography (CT) and magnetic resonance angiography have become the preferred screening tests for renal artery stenosis because initial studies suggested better sensitivity and specificity (Fig. 43-15). More recent data, however, indicate that even in experienced centers, these imaging modalities cannot reliably exclude renal artery stenosis. Gadolinium-enhanced MRI is contraindicated in patients with advanced CKD to avoid causing nephrogenic systemic fibrosis, a potentially fatal complication seen mainly in patients with low GFR.⁷⁰

MANAGEMENT. Balloon angioplasty (without stenting) is the treatment of choice for renal FMD (see also Chapter 60). But

pending better outcomes data, a conservative approach based on medical management of cardiovascular risk factors—with antihypertensive medication, statins, and antiplatelet therapy—is the cornerstone for the treatment of patients with atherosclerotic renal artery stenosis. The availability of ACE inhibitors and ARBs can be considered a double-edged sword; one edge provides better control of renovascular hypertension than may be possible with other antihypertensive medications, whereas the other edge exposes the already ischemic kidney to further loss of blood flow by inhibiting the high level of A II that was supporting its circulation. Other antihypertensive drugs may be almost as effective as ACE inhibitors and perhaps safer, but there are no comparative data. Medically refractory hypertension and progressive decline in renal function (ischemic nephropathy) currently are the only two firm indications for balloon angioplasty. Renal artery stenting should be avoided because it is no more effective than medical management and can cause complications.^{67,68}

Renin-Secreting Tumors

Composed of juxtaglomerular cells (conferring a histologic diagnosis of hemangiopericytoma), renin-secreting tumors occur mostly in young patients with severe hypertension, with very high renin levels in both peripheral blood and the kidney harboring the tumor, and with secondary aldosteronism manifested by hypokalemia. The tumor generally can be recognized by selective renal angiography, usually performed for suspected renovascular hypertension, although a few are extrarenal. More commonly, children with Wilms tumors (nephroblastoma) may have hypertension and high plasma renin and prorenin levels that revert to normal after nephrectomy.

ADRENAL AND OTHER CAUSES OF HYPERTENSION

Adrenal causes of hypertension (see Chapter 81) include primary excesses of aldosterone, cortisol, and catecholamines; more rarely, excess deoxycorticosterone is present with congenital adrenal hyperplasia. Together, these conditions cause less than 1% of all cases of hypertension in general practice, although primary aldosteronism accounts for 10% to 20% of patients referred to specialists for the evaluation of refractory hypertension. Despite their relative ease of recognition, each of these adrenal disorders can be easily overlooked because they are rare.

More problematic than the diagnosis of these adrenal disorders is the need to exclude their presence because of the increasing identification of an incidental solitary adrenal mass on abdominal imaging with CT or MRI.⁷¹ An adrenal “incidentaloma” is found on approximately 5% of abdominal CT scans obtained for nonadrenal indications. Some advocate that these findings require screening for hormonal excess (see Table 43-3). Most of these incidentalomas appear to be nonfunctional on the basis of normal basal adrenal hormone levels. When more detailed studies are done, however, a significant number show incomplete suppression of cortisol by dexamethasone—that is, subclinical Cushing disease that does not appear to progress to overt hypercortisolism but may associate with insulin resistance and osteopenia.

The probability of adrenal cancer varies by the imaging characteristics. The risk of cancer is low if a non-contrast-enhanced CT scan shows a tumor density of less than 10 Hounsfield units (HU), consistent with low-density lipid; if a MRI scan confirms a high lipid content by loss of signal on out-of-phase images; and if the tumor is smaller than 4 cm. Tumors 4 cm or larger should be resected because many are malignant.

FIGURE 43-15 Computed tomography angiogram with three-dimensional reconstruction, showing a severe proximal atherosclerotic stenosis of the right renal artery and mild stenosis of the left renal artery (A) and the classic “string-of-beads” lesion of fibromuscular dysplasia (bilateral in this patient) (B). (Courtesy Dr. Bart Domatch, Radiology Department, University of Texas Southwestern Medical Center, Dallas.)

Primary Aldosteronism and Other Forms of Mineralocorticoid-Induced Hypertension

Several syndromes with mineralocorticoid excess have been recognized (Table 43-5); primary aldosteronism is the most common. Debate continues about the prevalence of primary aldosteronism in an unselected hypertensive population, but most experts agree that patients with resistant hypertension commonly have the condition.⁷² Moreover, in keeping with the profibrotic effects of aldosterone, many more cardiovascular events occur in patients with primary aldosteronism than in patients with primary hypertension matched for age, sex, and blood pressure levels.

Recent studies have identified spontaneous and inherited potassium channel mutations in approximately one third of aldosterone-producing adenomas. The mutations make the potassium channel abnormally permeant to sodium, which depolarizes the adrenal glomerulosa cells to produce calcium entry—the signal for both aldosterone secretion and cell proliferation.⁷³

Pathophysiology of Mineralocorticoid Excess

In older series, the most frequently identified source of hyperaldosteronism was a solitary aldosterone-producing adenoma. More recently, measurements of plasma renin and aldosterone have identified milder forms of hyperaldosteronism, usually associated with bilateral adrenal hyperplasia (BAH).

Aldosterone excess from any source causes hypertension and renal potassium wastage, which should induce hypokalemia (Fig. 43-16), but most patients with aldosteronism caused by BAH are normokalemic. The lack of overt hypokalemia could exist because potassium wastage has lowered the serum potassium level, but not yet to hypokalemic levels; because with milder degrees of aldosteronism, as are typical with BAH, the excess of aldosterone induces hypertension without causing potassium wastage, a scenario that has never been experimentally or clinically recognized; or because the BAH relates to the typical progressive increase in adrenal nodular hyperplasia with age that has no relationship to hypertension. The third explanation would fit with the long-held belief that BAH is simply a form of low-renin hypertension—that is, primary hypertension with plasma renin levels that fall progressively with age while plasma aldosterone levels remain stable.

This explanation could account for the common finding of an increased aldosterone-to-renin ratio, caused not by increased aldosterone but by decreased renin, and by the presence of BAH in most normokalemic hypertensive patients.

Diagnosis

The three steps to the recommended evaluation of primary aldosteronism are screening, salt loading for biochemical confirmation, and adrenal vein sampling for localization.⁷⁴ Screening involves measurement of plasma renin and serum aldosterone. Despite the recommendation by a few experts that virtually all hypertensive patients be screened by an aldosterone-to-renin ratio measurement, only 1% will have a surgically correctable adenoma. Moreover, if screening is done, rather than using a ratio that could be high only because of a low renin level, a positive result should be based on both an elevated plasma aldosterone level (above 15 ng/dL) and a suppressed low renin level.

Screening is recommended only for hypertensive subjects who have a higher likelihood of aldosterone-producing adenoma, including those with unprovoked hypokalemia or excessive hypokalemia on diuretic therapy, a family history of aldosteronism, resistant hypertension, or an adrenal incidentaloma. Hyperaldosteronism occurs in as many as 20% of patients with resistant hypertension, with half of these having unilateral disease and thus qualifying as surgical candidates.

If the screening plasma aldosterone and renin levels are suggestive, the next step is an oral salt-loading suppression test to document the autonomy of hyperaldosteronism. If the suppression test result is abnormal, adrenal vein sampling by an experienced tertiary center is strongly recommended, to differentiate unilateral adenoma from bilateral hyperplasia and to confirm exactly which gland should be removed by laparoscopic surgery (Fig. e43-8). Because detection of microscopic adenomas may be below the resolution of CT scanning, and because minor adrenal nodularity and nonfunctioning adrenal incidentalomas are common, CT findings alone may lead to the wrong conclusion almost half of the time.⁷⁵

Differential Diagnosis: Mendelian Forms of Hypertension

In patients presenting with severe hypertension and hypokalemia, primary aldosteronism needs to be distinguished from rare forms of mineralocorticoid-induced hypertension that are inherited as mendelian traits. Clinical clues to the presence of syndromic hypertension are premature onset (often before 30 years of age), the severity of the hypertension (frequently dramatic), and a compelling family history indicative of mendelian inheritance. All these familial syndromes involve excessive activation of ENaC as a final common mechanism, caused either by gain-of-function mutations of ENaC or of the mineralocorticoid receptor, or by increased production or decreased clearance of the mineralocorticoid receptor ligands—aldosterone, as well as deoxycorticosterone and cortisol (Fig. 43-17).

TABLE 43-5 Syndromes of Mineralocorticoid Excess

Adrenal Origin
Aldosterone Excess (Primary)
Aldosterone-producing adenoma
Bilateral hyperplasia
Primary unilateral adrenal hyperplasia
Glucocorticoid-remediable aldosteronism (familial hyperaldosteronism, type I)
Adrenal carcinoma
Extra-adrenal tumors
Deoxycorticosterone Excess
Deoxycorticosterone-secreting tumors
Congenital adrenal hyperplasia
11 β -Hydroxylase deficiency
17 α -Hydroxylase deficiency
Cortisol Excess
Cushing syndrome from ACTH-producing tumor
Glucocorticoid receptor resistance
Renal Origin
Activating mutation of mineralocorticoid receptor
Pseudohypoaldosteronism, type II (Gordon)
11 β -Hydroxysteroid dehydrogenase deficiency
<i>Congenital:</i> apparent mineralocorticoid excess
<i>Acquired:</i> licorice, carbenoxolone

Cortisol = 306 µg/dL
A/C ratio = 13

FIGURE e43-8 Computed tomography showing a left adrenal mass (arrow) and nodularity to the right adrenal gland. Adrenal vein sampling confirmed the diagnosis of a left aldosterone-producing adenoma. IVC = inferior vena cava. (Case provided by Dr. Richard Auchus, Internal Medicine Department/Endocrinology Division, University of Texas Southwestern Medical Center, Dallas.)

FIGURE 43-17 Mendelian forms of hypertension that cause mineralocorticoid-induced hypertension. A I = angiotensin I; A II = angiotensin II; AME = apparent mineralocorticoid excess; GRA = glucocorticoid-remediable aldosteronism; DOC = deoxycorticosterone; ENaC = epithelial sodium channel; 11βHD = 11β-hydroxylase; 17αHD = 17α-hydroxylase; HEP = hypertension exacerbated by pregnancy; MR = mineralocorticoid receptor; PHA2 = pseudohypoaldosteronism type II; ROMK = rectifying outer medullary potassium channel; WNK = with no lysine kinases. The effect of PHA2 on the activity of the thiazide-sensitive Na⁺-Cl⁻ cotransporter in the distal collecting duct is not shown. See text for explanation. (Modified from Lifton RP, Gharavi AG, Geller DS: Molecular mechanisms of human hypertension. *Cell* 104:545, 2001.)

One type, familial glucocorticoid-remediable aldosteronism, results from recombination of genes encoding the aldosterone synthase enzyme (CYP11B2), normally found only in the outer zona glomerulosa, and the 11β-hydroxylase enzyme (CYP11B1) in the zona fasciculata. The chimeric gene induces an enzyme that catalyzes the synthesis of 18-hydroxylated cortisol in the zona fasciculata. The glucocorticoid suppressibility of the syndrome occurs because this zone is under the control of adrenocorticotrophic hormone (ACTH). Genetic testing for the chimeric gene should diagnose the syndrome, treatable by glucocorticoid suppression.

Another rare form is apparent mineralocorticoid excess caused by deficiency of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-OHSD2) in the renal tubule, where it normally converts cortisol, which can act on the mineralocorticoid receptor, to cortisone, which cannot. Persistence of high levels of cortisol induces all the features of mineralocorticoid excess. The 11β-OHSD2 enzyme may be congenitally absent (the syndrome of apparent mineralocorticoid excess) or inhibited by the glycyrrhizic acid contained in licorice. Another unusual syndrome with hypertension and hypokalemia but suppressed mineralocorticoid secretion is Liddle syndrome, in which the kidney reabsorbs excess sodium and wastes potassium because of a mutation in the beta or gamma subunits of the epithelial sodium channel.

In most of these cases, volume expansion and severe hypertension cause feedback suppression of plasma renin, and mineralocorticoid receptor activation leads to renal potassium wasting and hypokalemia. One exception is pseudohypoaldosteronism type II, in which the disease-causing mutation produces both low-renin and salt-sensitive hypertension caused by overactivity of the thiazide-sensitive Na⁺-Cl⁻ cotransporter in the distal collecting duct and hyperkalemia caused by underactivity of the renal outer medullary potassium channel.

Therapy

Patients with a solitary adenoma are candidates for tumor resection by laparoscopic surgery. Those with bilateral hyperplasia should be treated medically with an aldosterone antagonist (spironolactone

or eplerenone) and other antihypertensive drugs as needed. Aldosterone antagonists also are an option for patients with a solitary adenoma who do not want surgery or do not have access to a hospital with an interventionalist with experience in adrenal vein sampling. Laparoscopic adrenalectomy eliminates the need for antihypertensive medication in up to 50% of patients and reduces medication requirements in patients who may have coexisting primary hypertension or renal damage from prolonged exposure to elevated blood pressure and undiagnosed hyperaldosteronism.

Cushing Syndrome

Hypertension occurs in approximately 80% of patients with Cushing syndrome (see Chapter 81). If left untreated, it can cause marked LVH and congestive heart failure. As with hypertension of other endocrine causes, the longer it is present, the less likely it will improve when the underlying cause is relieved.

Mechanism of Hypertension. Blood pressure can increase for a variety of reasons. The secretion of mineralocorticoids can increase along with cortisol, which itself is a potent activator of the mineralocorticoid receptor. The excess cortisol can overwhelm the ability of renal 11β-OHSD2 to convert it to cortisone, which is not a mineralocorticoid receptor ligand; the excess cortisol overstimulates renal mineralocorticoid receptors to retain sodium and expand plasma volume. Cortisol stimulates the synthesis of renin substrate and the expression of A I receptors, which may cause enhanced pressor effects.

Diagnosis. The syndrome should be suspected in patients with truncal obesity, wide purple striae, thin skin, muscle weakness, and osteoporosis. If clinical features are suggestive, the diagnosis often can be either ruled out or virtually ensured by the measurement of free cortisol in a 24-hour urine sample, the simple overnight dexamethasone suppression test, or the determination of late-night salivary cortisol. Some cases of metabolic syndrome may be caused by subclinical Cushing syndrome.

Therapy. In approximately two thirds of patients with Cushing syndrome, the process begins with overproduction of ACTH by the pituitary, which leads to BAH. Although pituitary hyperfunction may reflect a hypothalamic disorder, most patients have discrete pituitary adenomas that can usually be resected by selective transsphenoidal microsurgery.

If an adrenal tumor is present, it should be removed surgically, with appropriate steroid coverage to avoid acute adrenal insufficiency. With earlier diagnosis and more selective surgical therapy, more patients with Cushing syndrome might be cured without the need for lifelong glucocorticoid replacement therapy and with permanent relief of their hypertension. Therapy may require a drug temporarily, but rarely permanently.

Congenital Adrenal Hyperplasia. Enzymatic defects may induce hypertension by interfering with cortisol biosynthesis. Low levels of cortisol lead to increased ACTH levels; this increases the accumulation of precursors proximal to the enzymatic block, specifically deoxycorticosterone, which induces mineralocorticoid hypertension. The more common of these is 11-hydroxylase deficiency, which has been attributed to various mutations in the gene and leads to virilization (from excessive androgens) and hypertension with hypokalemia (from excessive deoxycorticosterone). The other is 17-hydroxylase deficiency, which also causes hypertension from excess deoxycorticosterone, in addition to failure of secondary sexual development because sex hormones are also deficient. Affected children are hypertensive, but the defect in sex hormone synthesis may not become obvious until pubertal failure is recognized in adolescence.

Pheochromocytoma and Paraganglioma

Pheochromocytomas are rare catecholamine-secreting tumors of the adrenal chromaffin cells; paragangliomas are even rarer extra-adrenal tumors of the sympathetic or vagal ganglion cells (see Chapter 81). For clinical purposes, the term *pheo* generally refers to any catecholamine-secreting tumor, whether a true adrenal pheochromocytoma or a functional extra-adrenal paraganglioma. The wild fluctuations in blood pressure and dramatic symptoms of pheo usually alert both the patient and physician to the possibility of this diagnosis (Table 43-6). Such fluctuations, however, may be missed, or as occurs in 50% of patients, the hypertension may be persistent. On one hand, the spells typical of a pheochromocytoma (with headache, sweating, palpitations, and pallor) may be incorrectly attributed to migraine, menopause, or panic attacks. On the other hand, most patients with severe paroxysmal hypertension do not have a pheochromocytoma

TABLE 43-6 Features Suggestive of Pheochromocytoma

Hypertension, Persistent or Paroxysmal
Markedly variable blood pressures (\pm orthostatic hypotension)
Sudden paroxysms (\pm subsequent hypertension) in relation to:
Stress: anesthesia, angiography, parturition
Pharmacologic provocation: histamine, nicotine, caffeine, beta blockers, glucocorticoids, tricyclic antidepressants
Manipulation of tumors: abdominal palpation, urination
Rare patients persistently normotensive
Unusual settings
Childhood, pregnancy, familial
Multiple endocrine adenomas: medullary carcinoma of the thyroid (MEN-2), mucosal neuromas (MEN-2B)
Von Hippel-Lindau syndrome
Neurocutaneous lesions: neurofibromatosis
Associated Symptoms
Sudden spells with headache, sweating, palpitations, nervousness, nausea, vomiting
Pain in chest or abdomen
Associated Signs
Sweating, tachycardia, arrhythmia, pallor, weight loss

but rather marked anxiety. When they are correctly diagnosed and treated, most pheos are curable. When they are undiagnosed or improperly treated, they can be fatal.^{76,77} See Chapter 81 for details regarding the pathophysiology, diagnosis, and treatment of pheochromocytoma.

Other Causes of Hypertension

Among the host of other possible causes of hypertension, one that probably is becoming more common is the ingestion of various drugs—prescribed (e.g., cyclosporine, tacrolimus, erythropoietin), over the counter (e.g., ephedra), and illicit (e.g., cocaine, methamphetamine). As previously noted, obstructive sleep apnea also commonly causes substantial, and often reversible, hypertension.

Coarctation of the Aorta

Congenital narrowing of the aorta (see Chapter 62) can occur at any level of the thoracic or abdominal aorta but typically localizes just beyond the origin of the left subclavian artery or distal to the insertion of the ligamentum arteriosum. With less severe postductal lesions, symptoms may not appear until the teenage years or later, particularly during pregnancy. Hypertension in the arms, weak or absent femoral pulses, and a loud murmur heard over the back classically characterize coarctation. The pathogenesis of the hypertension can involve more than simple mechanical obstruction and probably includes a generalized vasoconstrictor mechanism. The lesion can be detected by echocardiography, and MRI or contrast aortography proves the diagnosis. Once it is repaired, patients may continue to have hypertension that requires careful monitoring and treatment.

Hormonal Disturbances

As many as half of patients with various hormonal disturbances, including acromegaly, hypothyroidism, and hyperparathyroidism, have hypertension (see Chapter 81). Diagnosis of the last two conditions has been made easier by readily available blood tests, and affected hypertensive patients can be relieved of their high blood pressure by correction of the hormonal disturbance. Such relief occurs more frequently in patients with hypothyroidism than in those with hyperparathyroidism.

FUTURE PERSPECTIVES

Blood pressure measurement will become more accurate for diagnosis, cardiovascular risk stratification, and clinical decision making

with the greater use of out-of-office measurements and assessments of vascular health by measures of vascular compliance, central aortic pressure, and inflammatory biomarkers. Renal denervation will require further rigorous clinical evaluation to determine its role in the treatment of hypertension.

ACKNOWLEDGMENT

The author wishes to thank Dr. Norman M. Kaplan, who wrote portions of previous editions of this chapter (“Adrenal and Other Causes of Hypertension,” “Hypertensive Diseases of Women”).

FUTURE PERSPECTIVES, 975**REFERENCES, 975****GUIDELINES, 977**

Hypertension remains the most common diagnosis in adult outpatient medicine and the most common indication for prescription drugs. Lifestyle modification, particularly at the societal level, can prevent or delay the development of hypertension. Yet hypertension is becoming more prevalent in both developed and developing countries and remains poorly controlled in the United States and abroad.^{1,2}

Reductions in high blood pressure (BP) lead to large reductions in the risk for stroke, heart failure, renal failure, aortic dissection, coronary events, and death. These benefits apply to all hypertensive patient groups regardless of age, race/ethnicity, sex, or severity of hypertension (**Fig. 44-1**). Except for some cases of secondary hypertension, most cases of hypertension cannot be cured. Yet many tools permit management of hypertension: lifestyle modifications, antihypertensive drugs, and now possibly cardiovascular (CV) interventions such as renal denervation. We will discuss their deployment based on the available evidence. Then, because of the recent release of different sets of hypertension guidelines both in the United States and abroad,³⁻¹² we provide a practical clinical approach to the management of hypertensive patients.

LIFESTYLE MODIFICATION

Lifestyle choices and interventions can influence BP and furnish a foundation for prevention and treatment of hypertension. The current evidence base regarding dietary patterns and specific dietary components has sufficient strength to merit recommendations both on a population, public health level and on the management of individual patients. Evidence regarding physical activity interventions has lagged behind the evidence base on dietary approaches to the treatment of hypertension. Limitations regarding lifestyle and BP management require consideration. First, few studies have examined the effects of lifestyle interventions on CV outcomes; most rely on BP as a surrogate endpoint. Second, the effect of lifestyle modification on BP and CV outcomes may vary depending on sex, age, and ethnicity.¹³⁻¹⁶ Few studies of lifestyle intervention have incorporated sufficient numbers of older adults or minority populations to provide strong evidence for specific recommendations for these important groups.

Dietary Interventions for Blood Pressure Control

Traditional approaches to the study of diet and BP have focused on individual nutrients. As considered in depth in **Chapter 46**, a more recent concept recognizes that consumption of specific nutrients occurs in the context of food in a diet. Hence the contemporary approach to studies of nutrition and health focuses more on dietary patterns rather than on specific nutrients. This section first considers dietary patterns that have undergone evaluation with respect to BP control, followed by individual macronutrients and micronutrients of particular interest in this regard.

Two dietary patterns in particular have undergone contemporary and rigorous study in relation to BP control: the Mediterranean diet pattern and the Dietary Approaches to Stop Hypertension (DASH) diet pattern. **Table 44-1** provides brief definitions of the Mediterranean and DASH diet patterns derived from the 2013 American Heart Association/American College of Cardiology (AHA/ACC) guideline on lifestyle management to reduce CV risk.¹⁷ (See **Chapter 46** and references 18 and 19 for further detail.)

The Mediterranean Diet Pattern

The recent publication of the PREDIMED (Prevención con Dieta Mediterránea) study stimulated interest among CV specialists in the potential benefits of a Mediterranean diet.²⁰ This trial showed an overall benefit in CV outcomes in the dietary intervention groups driven by a decrease in stroke, an endpoint closely associated with BP. The comparator group consumed a low-fat diet. BP data are not yet available from this study, yet at baseline more than 80% of the participants had hypertension, defined as systolic blood pressure (SBP) higher than 140 mm Hg, diastolic blood pressure (DBP) of 90 mm Hg or higher, or the use of antihypertensive therapy. Consumption of a Mediterranean diet pattern correlated with improvement in numerous biomarkers associated with CV benefit—ranging from reductions in BP²¹ to anti-inflammatory effects, as assessed by reduced C-reactive protein levels.²² Yet the most recent AHA/ACC guidelines on lifestyle management assessed the strength of evidence as being low regarding consumption of a Mediterranean diet pattern versus a low-fat dietary pattern despite reductions in SBP ranging from 2 to 7 mm Hg following an intervention.

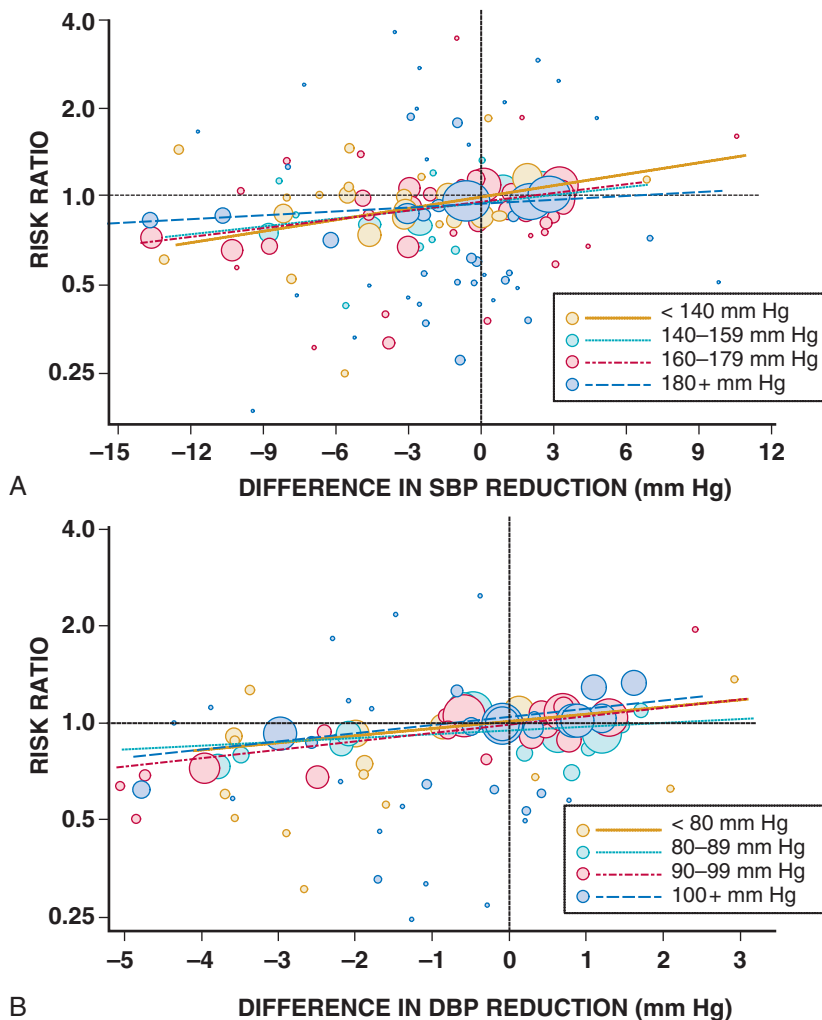

FIGURE 44-1 Comparison of the associations between change in BP and the risk ratio reduction in total major CV events according to categories of SBP (**A**) and DBP (**B**). The area of each circle is proportional to the inverse variance of the log odds ratio. The fitted line represents the summary meta-regression for total major CV events. (From Czerlichow E, Zanchetti A, Turnbull F, et al: The effects of blood pressure reduction of different blood pressure-lowering regimens on major cardiovascular events according to baseline blood pressure: Meta-analysis of randomized trials. *J Hypertens* 29:4, 2011.)

TABLE 44-1 Descriptions of Dietary Patterns

Mediterranean Pattern
There is no uniform definition of the Mediterranean diet in the RCTs and cohort studies examined. The most common features in these studies were diets that were higher in fruits (particularly fresh fruits), vegetables (emphasizing root and green varieties), whole grains (cereals, breads, rice, or pasta), and fatty fish (rich in omega-3 fatty acids); were lower in red meat (and emphasizing lean meats); had lower-fat or fat-free dairy products substituted for higher-fat dairy foods; and had oils (olive or canola), nuts (walnuts, almonds, or hazelnuts), or margarines blended with rapeseed or flaxseed oil in lieu of butter and other fats. The Mediterranean patterns examined tended to be moderate in total fat (32% to 35% of total calories), relatively low in saturated fat (9% to 10% of total calories), high in fiber (27 to 37 g/day), and high in polyunsaturated fatty acids (particularly omega-3 fatty acids).
Dietary Approaches to Stop Hypertension Pattern
The DASH dietary pattern is high in vegetables, fruits, low-fat dairy products, whole grains, poultry, fish, and nuts and low in sweets, sugar-sweetened beverages, and red meats; low in saturated fat, total fat, and cholesterol; and rich in potassium, magnesium, and calcium, as well as in protein and fiber.

Modified from the Eckel RH, Jakicic JM, Ard JD, et al: 2013 AHA/ACC guideline on lifestyle management to reduce cardiovascular risk: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Clin Cardiol* 2013 Nov 7. pii: S0735-1097(13)06029-4. doi: 10.1016/j.jacc.2013.11.003. [Epub ahead of print.]

The DASH Diet Pattern

The DASH diet (Table 44-1) evolved from studies supported by the U.S. National Heart, Lung and Blood Institute (NHLBI). These randomized, controlled DASH feeding studies showed that this dietary pattern could lower SBP by more than 5 mm Hg in adults with moderate hypertension when compared with the control diet.²³ The effect size was larger in members of minority groups than in white subjects participating in the studies. A follow-up study known as DASH-Sodium tested the hypothesis that salt restriction in addition to the DASH diet would further reduce BP by evaluating three different levels of sodium content (3, 2.4, or 1.5 g daily). Over the 30 days of intervention, the low-salt diet produced a drop in SBP of almost 9 mm Hg.²⁴ The 2013 AHA/ACC guidelines consider the strength of evidence high for adherence to the DASH diet in individuals with hypertension.¹⁷

Sodium Consumption and Blood Pressure

The relationship between sodium and BP provides a particularly important example of the necessity of considering public health interventions, as well as lifestyle change, in individual patients to control CV risk. The effects of sodium intake on BP and the CV benefits of limiting sodium consumption have proved contentious and controversial over many decades. In May 2013, the U.S. Institute of Medicine (IOM) released a report on sodium intake in populations in which the evidence in this regard was assessed.²⁵ The report particularly addressed the concern that more stringent dietary restriction of sodium might be associated with *increased* overall health risk. The IOM committee identified many methodologic concerns about the evidence base regarding sodium intake and health, yet the report concluded that the weight of the evidence supported a link between higher levels of sodium consumption and CV risk but judged the evidence insufficient to support a restriction in sodium intake to below 2.3 g daily. Of particular interest to cardiologists, this evidentiary IOM review suggested that low sodium might worsen outcomes in individuals with severe heart failure. Ultimately, the IOM panel did not interpret the current evidence base as supportive of efforts to lower dietary sodium to 1.5 g daily for the general public. They called for further investigation to probe the health effects of salt intake in the range of 1.5 to 2.3 g daily.

The 2013 AHA/ACC lifestyle management guidelines concluded that in adults 25 to 80 years of age with an SBP of 120 to 159 mm Hg, reducing sodium intake lowers BP.¹⁷ They further found the evidence strong that for adults 30 to 80 years of age with or without hypertension, reduction of sodium intake by approximately 1 g daily lowers SBP by 3 to 4 mm Hg. Despite specific concerns, they judged the strength of evidence insufficient to support an association between sodium intake and the development of heart failure or that it could influence CV outcomes in patients with established heart failure.

Potassium Intake and Blood Pressure

Considerable observational data suggest an association between high potassium intake and lower BP. Increased consumption of potassium may lower BP, particularly in blacks as compared with whites. Even though the American Society of Hypertension (ASH) recommends an increase in potassium intake to 4.7 g daily (the level provided in the DASH diet),¹³ the 2013 AHA/ACC lifestyle guidelines find the strength of evidence insufficient to establish a relationship between increased dietary potassium and lower BP or altered risk for coronary heart disease, heart failure, or CV mortality.¹⁷

Carbohydrate Consumption and Blood Pressure

The observational data base yields disparate data regarding the effect of the amount and composition of dietary carbohydrates on BP. OmniHeart (Optimal Macronutrient Intake Trial to Prevent Heart Disease) showed that exchanging dietary carbohydrate for either protein or monounsaturated fat lowers BP. This study included 164 subjects with an SBP at baseline of 120 to 159 mm Hg.²⁶ Albeit small, this well-designed and well-conducted study showed not only a decrease in BP but also a concomitant improvement in lipid profile. The 2013 AHA/ACC lifestyle guidelines considered the strength of evidence insufficient to make recommendations regarding the potential benefits of low-glycemic diets versus high-glycemic diets for individuals without diabetes.¹⁷

Ethanol Intake and Blood Pressure

A large body of observational evidence supports higher levels of BP in association with greater alcohol intake. A meta-analysis of self-reported decreases in alcohol intake showed that it lowered SBP by more than 3 mm Hg and DBP by more than 2 mm Hg.²⁷ On the basis of the observational data and this meta-analysis, the ASH recommends limiting consumption to one alcoholic drink per day in women and no more than two alcoholic drinks per day in men.

Sugar-Sweetened Beverages

The increased consumption of sugar-sweetened beverages (SSBs) worldwide has been linked to the epidemic of obesity, particular in the young.^{28,29} Evidence also supports an association between increased consumption of SSBs and higher levels of BP. A prospective analysis of the PREMIER study showed that after adjustment for confounders, a reduction in SSBs by one serving daily resulted in an almost 2-mm Hg decrease in SBP.³⁰ An international study of the effect of macronutrients and micronutrients on BP reported cross-sectional associations of SSBs with BP and found that one serving of an SSB daily was associated with a difference in SBP of greater than 1.5 mm Hg. This analysis showed a direct relationship between fructose and glucose intake with BP.³¹ These observational and trial data suggest that curbing SSB consumption could lower BP in the population and that restriction of SSB intake should be considered in individuals with established hypertension.

Other Macronutrients and Micronutrients and Blood Pressure Control

Many studies have linked other macronutrients and micronutrients with BP control. The foregoing discussion has considered those supported by the strongest evidence base. **Table 44-2** provides a more ample list of the dietary factors and dietary patterns implicated in BP control, with estimates of the strength of the evidence adapted from the ASH position paper on dietary approaches to lower BP.¹³

Obesity/Body Weight

Considerable observational data support a relationship between body mass index (BMI) and the development of hypertension. Overall, adiposity was strongly associated with incident hypertension in both blacks and whites in the NHANES (National Health and Nutrition Evaluation Survey) data.³² Visceral adiposity and other ectopic fat deposits may also be associated with hypertension. As with other components of “metabolic syndrome,” hypertension may develop in Asians at a lower waist circumference than in whites or blacks. In the Nurses’ Health Study, which monitored more than 80,000 women for 14 years, BMI correlated most strongly with incident hypertension among the six risk factors evaluated—with a hazard ratio of 4.7 for obese women versus those with a BMI of less than 23 kg/m². The population attributable risk for the development of hypertension with a BMI higher than 25 kg/m² was 50% (95% confidence interval, 49% to 52%). These data suggest that obesity constitutes a major risk for hypertension and that control of body weight might eliminate a great amount of the morbidity associated with hypertension and avoid pharmacotherapy with its attendant unwanted effects (**Table 44-3**).³³

TABLE 44-2 Effects of Dietary Factors and Dietary Patterns on Blood Pressure: Summary of the Evidence

	HYPOTHESIZED EFFECT	EVIDENCE
Weight	Direct	+/+
Sodium chloride (salt)	Direct	+/+
Potassium	Inverse	+/+

Physical Activity

Epidemiologic and observational studies have linked insufficient physical activity to increased CV risk. Because physical activity influences both CV fitness and body weight and visceral adiposity, the mechanisms through which exercise interacts with CV risk factors—and potentially with outcomes—remain difficult to define. Moreover, the effects of physical activity depend on whether the activity involves aerobic exercise, strength training, or a combination of both. In the case of BP control, the response to physical activity may be heterogeneous. Some individuals may have increases in BP when they undergo exercise training, whereas others may have reductions. The effects of physical activity on BP also depend on whether acute

effects during or immediately following exercise are measured versus chronic changes in this risk factor.³⁴ An occasional hypertensive patient may even experience symptomatic hypotension immediately after exercise, thereby requiring a reduction in the dose of BP medication. As in other aspects of lifestyle intervention, few studies have examined actual CV outcomes rather than biomarkers of surrogate endpoints. A recent meta-epidemiologic analysis that included 4 exercise meta-analyses and 12 drug meta-analyses, including more than 300 randomized, controlled trials involving more than 300,000 participants, found that exercise interventions and some drug interventions provided similar mortality benefits.³⁵ Some evidence supports a genetic basis in determining the BP response to exercise, but no clinically applicable findings have emerged from such genomic analyses thus far.³⁶ Some evidence supports a decrease in biomarkers of inflammation with interval exercise training in patients with hypertension.³⁷

The 2013 AHA/ACC guideline summarizes an extensive evidentiary review that includes the 2008 report of the Physical Activity Guidelines Advisory Committee of the U.S. Department of Health and Human Services.³⁸ The 2013 guideline database included 15 recent meta-analyses. The guideline states that in adults with or without hypertension, aerobic physical activity reduces SBP up to 5 mm Hg, with high strength of evidence. The committee concluded that the evidence was insufficient to provide an assessment of the effect of resistance exercise training on BP. They similarly pointed to a paucity of data regarding combined aerobic and resistance exercise intervention on regulation of BP. The committee provided a grade B recommendation that all adults engage in regular physical activity (Table 44-4).

Cigarette Smoking

The effect of cigarette smoking on hypertension and outcomes in hypertensive patients remains difficult to define because of confounding by increases in waist girth with smoking cessation.³⁹ Each cigarette evokes a transient pressor response that dissipates over the next hour. Despite the lack of precise mechanistic information regarding smoking and BP control, the overwhelming deleterious effect of smoking on CV risk, as well as the public health benefits of preventing the start of smoking and promoting cessation of smoking, renders this issue moot for public health and individual patient management.

Barriers to Adoption and Maintenance of Lifestyle Change and Possible Solutions

In practice, encouraging sustainable lifestyle change has proved extremely difficult. Substantial recent efforts have explored strategies and tools for encouraging the adoption of healthier lifestyles, including weight control, diet, and physical activity. Some challenges to lifestyle change identified in the literature will resonate with practitioners. Individuals express a low desire for, interest in, or awareness of dietary change, including weight loss, decreased sodium intake, smoking cessation, or reduced alcohol consumption. Barriers to adoption of physical activity recommendations include comorbid conditions that limit physical activity, as well as limited time.⁴⁰ Contemporary adjuncts to the usual medical model for lifestyle intervention include Internet-based interventions, which are currently under intense evaluation.^{38,41-44} Given its critical importance for CV and metabolic health, effective measures for implementing and sustaining lifestyle change should remain an important goal for research and process improvement.

ANTIHYPERTENSIVE DRUGS

Although all hypertensive individuals should heed the lifestyle measure outlines above, most will also require drug therapy to optimize outcomes. Metaregression analyses of hundreds of thousands of hypertensive patients in randomized controlled trials (RCTs) have

TABLE 44-4 Diet and Physical Activity Recommendations for Lowering Blood Pressure

Dietary Recommendations		
<ol style="list-style-type: none"> Advise adults who would benefit from BP lowering to consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts; and limits intake of sweets, SSBs, and red meat: <ol style="list-style-type: none"> Adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus). COR = class of recommendation; LOE = level of evidence.
Modified from the Eckel RH, Jakicic JM, Ard JD, et al: 2013 AHA/ACC guideline on lifestyle management to reduce cardiovascular risk: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Clin Cardiol* 2013 Nov 7; pii: S0735-1097(13)06029-4. doi: 10.1016/j.jacc.2013.11.003. [Epub ahead of print.]

indicated that reduction in BP (hemodynamic load) explains most of the CV benefits of treating hypertension, with minor differences noted across major drug classes (Fig. 44-1).⁴⁵ Reduced SBP confers the greatest magnitude of benefit in lowering the risk for stroke.

Oral antihypertensive drugs approved by the U.S. Food and Drug Administration (FDA) are shown in Table 44-5. Contraindications to specific drug classes are presented in Table 44-6. Preferred antihypertensive drug classes for specific patient subsets are listed in Table 44-7.

First-Line Drug Classes

Most new practice guidelines³⁻¹² (see Guidelines following this chapter) recommend initiating treatment of hypertension with one or more of the following three classes of first-line BP-lowering agents: (1) calcium channel blockers (CCBs); (2) renin-angiotensin system (RAS) inhibitors, either angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs); and (3) thiazide-type diuretics. Many RCTs and meta-analyses have shown that these drugs reduce the risk for nonfatal and fatal CV events. They have additive or synergistic effects when used in combination. Although beta-adrenergic blockers are first-line drugs for angina and heart failure, experts disagree whether they should be included among the first-line drugs for uncomplicated hypertension because of their inferior stroke protection and increased risk for incident diabetes. Experts differ in the emphasis placed on thiazide-type diuretics.

TABLE 44-5 Oral Antihypertensive Drugs

DRUG	DOSE RANGE, TOTAL MG/DAY (DOSES PER DAY)	DRUG	DOSE RANGE, TOTAL MG/DAY (DOSES PER DAY)
Diuretics		Angiotensin-Converting Enzyme Inhibitors

TABLE 44-6 Contraindications to the Use of Specific Antihypertensive Drugs

DRUG	COMPELLING	POSSIBLE
Diuretics (thiazide)	Gout	Metabolic syndrome Glucose intolerance Pregnancy Hypercalcemia Hypokalemia
Beta blockers	Asthma Atrioventricular block (grade 2 or 3)	Metabolic syndrome Glucose intolerance (except for vasodilating beta blockers) Athletes and physically active patients Chronic obstructive pulmonary disease
Dihydropyridine calcium channel blockers		Tachyarrhythmia Heart failure
Nondihydropyridine calcium channel blockers	Atrioventricular block (grade 2 or 3, trifascicular block) Severe left ventricular heart dysfunction Heart failure	
Angiotensin-converting enzyme inhibitors	Pregnancy Angioedema Hyperkalemia Bilateral renal artery stenosis	Women with childbearing potential
Angiotensin receptor blockers	Pregnancy Hyperkalemia Bilateral renal artery stenosis	Women with childbearing potential
Aldosterone antagonists	Acute or severe renal failure (estimated glomerular filtration rate < 30 mL/min) Hyperkalemia	

TABLE 44-7 Preferred Antihypertensive Drugs for Specific Conditions

CONDITION	DRUG OR DRUGS
Patients with prehypertension	ARB?
Hypertensive patients in general	CCB, ACEI or ARB, D
Hypertension in older patients	CCB, ACEI or ARB, D
Hypertension with LVH	ARB, D, CCB
Hypertension in patients with diabetes mellitus	CCB, ACEI or ARB, D
Hypertension in patients with diabetic neuropathy	ARB, D
Hypertension in patients with nondiabetic chronic kidney disease	ACEI, BB, D
BP reduction for secondary prevention of coronary events	ACEI, CCB, BB, D
BP reduction for secondary prevention of stroke	ACEI + D, CCB
BP for patients with heart failure	D, BB, ACEI, ARB, aldosterone antagonists
Pregnancy	Methyldopa, BB, CCB
Aortic aneurysm	BB
Atrial fibrillation, ventricular rate control	BB, nondihydropyridine CCB

BB = beta blocker; D = diuretic; LVH = left ventricular hypertrophy.

Modified from Mancia G, Fagard R, Narkiewicz K, et al: 2013 ESH/ESC guidelines for the management of arterial hypertension: The Task Force for the Management of Arterial Hypertension of the European Society of Hypertension (ESH) and of the European Society of Cardiology (ESC). *Eur Heart J* 31:1281, 2013.

Calcium Channel Blockers for Hypertension

CCBs are very popular antihypertensive drugs. They are generally well tolerated, do not require monitoring with blood tests, and have proved safe and effective in many large RCTs. CCBs also have anti-anginal and some antiarrhythmic effects and seem to provide more protection against stroke than other antihypertensive agents do. More recent data have allayed concerns raised in the mid-1990s that CCBs cause excess coronary events. For example, ALLHAT (Antihypertensive Lowering to Prevent Heart Attack Trial) and subsequent RCTs showed that CCBs (represented by amlodipine) prevent coronary events as effectively as diuretics and RAS blockers do.⁴⁶

Mechanism of Action

All CCBs block the opening of voltage-gated (L-type) Ca^{2+} channels in cardiac myocytes and vascular smooth muscle cells. They lower BP by causing peripheral arterial dilation, with the rank order of potency being dihydropyridines > diltiazem > verapamil.

Clinical Use

Amlodipine, by far the best studied of the dihydropyridine CCBs, has undergone evaluation in multiple RCTs. In ALLHAT, amlodipine was equivalent to chlorthalidone (a potent thiazide-like diuretic) and lisinopril (an ACEI) in protecting against nonfatal coronary events, stroke, and death but provided less protection against heart failure.⁴⁶ Advantages of amlodipine include predictable dose-dependent potency, once-daily dosing because of its long half-life, tolerability, and cost. Some retail drug stores offer generic amlodipine for \$10 per month. Unlike diuretics and RAS inhibitors, a high-salt diet or concurrent nonsteroidal anti-inflammatory drug (NSAID) therapy does not compromise the effectiveness of dihydropyridine CCBs. These drugs have some diuretic action (because of dilation of the afferent renal arteriole), which may reduce requirements for additional diuretic therapy in patients with mild hypertension. Unlike ACEIs, they are equally potent in lowering BP and preventing hypertensive complications in black and nonblack patients.⁴⁶ ASCOT (Anglo-Scandinavian Cardiovascular Outcomes Trial)⁴⁷ and the ACCOMPLISH (Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic Hypertension)⁴⁸ trial indicated that amlodipine plus an ACEI is one of the most effective drug combinations for preventing CV complications of hypertension. For comparable reductions in office (and ambulatory) BP, amlodipine/ACEI combination therapy improved CV outcomes better than did beta blocker/thiazide combination therapy in ASCOT or than did ACEI/thiazide combination therapy in ACCOMPLISH. Multiple fixed-dose single-pill combinations of amlodipine with an ACEI or an ARB have become available; some have added a thiazide for triple therapy.

Dihydropyridine CCBs such as amlodipine are less renoprotective than ACEIs or ARBs in patients with proteinuric chronic kidney disease (CKD); such patients should not receive amlodipine as first-line therapy, but a CCB may be useful as adjunctive therapy after initiation of appropriate first-line therapy with an ACEI or ARB and a diuretic. Verapamil is weakly antihypertensive and has limited usefulness because of dose-dependent constipation. Diltiazem is intermediate in potency between verapamil and the dihydropyridines and is usually well tolerated.

Side Effects

The principal side effect of the dihydropyridines is dose-dependent ankle edema. With amlodipine, ankle edema is far more common with a 10-mg dose than with 2.5- or 5-mg doses. This edema appears to be vasogenic because of selective arterial dilation and can respond to concomitant therapy with an ACEI or ARB that causes balanced arterial and venous dilation. Long-acting dihydropyridine CCBs are rarely associated with flushing and headache. All CCBs can cause gingival hyperplasia, a rare side effect that is reversible if detected early but can lead to several dental problems if the CCB therapy is not suspected as the cause. Verapamil and diltiazem can impair cardiac conduction, especially in older patients also receiving digoxin, beta blockers, or central sympatholytic agents.

Renin-Angiotensin Inhibitors for Hypertension: Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Direct Renin Inhibitors

RAS inhibitors are among the best tolerated of the antihypertensive drugs. The recent large study ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial) showed comparable effects of the ACEI ramipril and the ARB telmisartan with regard to reducing CV events and preventing deterioration of renal function in high-risk hypertensive patients.⁴⁹ Other data suggest that ARBs may provide slightly more protection against stroke. However, in general, the outcomes of many RCTs have not substantiated the hypothesis that RAS inhibitors produce important BP-independent benefits in hypertensive patients. The direct renin inhibitor (DRI) aliskiren is one of the newest BP drugs, but there are no completed or ongoing RCTs of aliskiren monotherapy. “Dual RAS blockade”—either with an ACEI plus an ARB or with aliskiren plus an ACEI or ARB—is now contraindicated. These combinations must be avoided because they produce more hypotension, accelerate the decline in renal function, and cause more hyperkalemia (see below).

Mechanisms of Action

ACEIs block conversion of the inactive precursor angiotensin I (A I) to A II. ARBs block the action of A II on the type 1 angiotensin receptor. The DRI aliskiren blocks the conversion of prorenin to renin, thereby blocking RAS activation at its origin. High levels of circulating prorenin may stimulate A I receptor-independent signaling pathways, which are both potentially beneficial and potentially harmful.

Clinical Use

ACEIs are easy to use and have a rather flat dose-response curve. In ALLHAT, ACEI monotherapy with lisinopril was equivalent to amlodipine or chlorthalidone monotherapy in all aspects except for producing a smaller reduction in BP and thus less stroke protection in black hypertensive individuals.⁴⁶ As monotherapy, ACEIs are generally less effective in lowering BP in black patients and in older patients with low-renin hypertension, but they are quite effective in these groups when combined with a low-dose diuretic or CCB. In meta-analyses, ACEIs have been shown to be equivalent to CCBs in protecting against coronary events, slightly less effective in protecting against stroke, but better in protecting against heart failure.⁵⁰

ARBs may confer the same benefits as ACEIs in treating hypertension while avoiding the ACEI-related cough (see below). Current \$4 per month formularies include generic ACEIs but no ARBs. Losartan is the first ARB to become generic.

ACEIs and ARBs have become standard first-line antihypertensive therapy for patients with diabetic and nondiabetic CKD, but evidence has shown that RAS inhibitors provide superior renal protection than other antihypertensive agents do only for proteinuric CKD,¹¹ as in AASK (African American Study of Kidney Disease). Head-to-head comparison in the large study ONTARGET has indicated that ACEIs and ARBs have comparable effects on renal function.⁵¹ For hypertensive individuals with normal baseline renal function, ACEIs and ARBs have not demonstrated greater renoprotective effects than other classes of antihypertensive agents.⁵²

Although animal studies and retrospective meta-analyses have suggested that ACEIs and ARBs may prevent or slow progression from glucose intolerance to type 2 diabetes, the trial evidence is weak.¹¹ In meta-analysis, ARBs produce more regression of left ventricular hypertrophy (LVH) than do other antihypertensive drugs.⁵³

Side Effects

All RAS inhibitors are contraindicated in pregnancy because they cause fetal renal agenesis and other birth defects. The most common side effect of ACEIs is a dry cough, which is more common in black patients and more common still in Asian patients. ACEIs block the degradation of bradykinin, which activates the nociceptive sensory fibers in the lungs that trigger the cough. Bradykinin may also underlie ACEI-induced angioedema, a much less common adverse effect. If a cough develops in a patient taking an ACEI who needs RAS blockade, an ARB should be substituted. Only isolated instances of cough or

angioedema associated with ARBs have been reported. ACEIs and ARBs can provoke hyperkalemia in the setting of CKD or diabetes with type 4 renal tubular acidosis. In patients with stage 3 CKD with proteinuria, initiation of ACEI or ARB therapy is often associated with a small transient increase in serum creatinine; therapy can be continued unless the elevation in creatinine is greater than 30%, an indication to decrease the dose or temporarily withhold therapy.

ACEIs and ARBs have been used together for extra renal protection in proteinuric patients. Yet the results of ONTARGET showed that such dual RAS blockade increases serious renal outcomes, hypotensive events, and hyperkalemia when compared with monotherapy with either agent alone.⁵¹ The combination of an ACEI or ARB with aliskiren entails similar risks,^{54,55} which has caused the FDA to issue a black box warning and to halt marketing of the fixed-dose combination. Moreover, the COOPERATE (Combination Treatment of Angiotensin-II Receptor Blocker and Angiotensin-Converting-Enzyme Inhibitor in Non-diabetic Renal Disease) trial, which had provided the earlier evidence supporting the practice of dual RAS blockade, was retracted from publication in *Lancet* on the basis of scientific misconduct.⁵⁶

Diuretics for Hypertension

Diuretics are among the oldest and most effective antihypertensive medications. Even though diuretics are inexpensive, generic forms of most other BP drug classes have also become inexpensive. Diuretics have been the cornerstone of antihypertensive therapy since the first Joint National Committee (JNC) report in 1977 through the 2003 JNC 7 report. The 2103 scientific advisory statement from the AHA, ACC, and Centers for Disease Control and Prevention (CDC)⁷ still recommends thiazide diuretics as the best choice to initiate antihypertensive therapy, whereas the 2014 report of the JNC 8 committee members⁹ and most other recent guidelines list them as one of three first-line choices (see Table 44G-2 in the Guidelines section). Multiple RCTs have shown that thiazide-type diuretics reduce coronary events, strokes, and heart failure in elderly patients.⁴ In ALLHAT, the diuretic was equally effective as the ACEI and CCB in preventing coronary events and strokes, more effective than the CCB in preventing heart failure, and in black patients, more effective than the ACEI in preventing strokes. When combined with most other classes of antihypertensive drugs, diuretics exert a synergistic effect on BP reduction, but in the more recent ACCOMPLISH trial, the combination of an ACEI with a CCB yielded better outcomes than did combination with hydrochlorothiazide (HCTZ).⁴⁸ Despite the popularity of HCTZ in the United States, the bulk of clinical trials supporting the benefits of diuretic therapy for hypertension did not use HCTZ but rather chlorthalidone, a thiazide-like diuretic that is more potent and longer lasting than HCTZ (see below). Thiazide and thiazide-like diuretics (especially in higher doses) cause more metabolic side effects and more erectile dysfunction than do ACEIs or CCBs and have higher discontinuation rates.⁵⁷

Mechanisms of Action

With initiation of diuretic therapy, contraction of blood volume causes the initial fall in BP. With continued therapy, blood volume is partially restored, and vasodilator mechanisms (e.g., opening of adenosine triphosphate [ATP]-sensitive K⁺ channels) sustain the antihypertensive action. Loop diuretics block Na⁺-K⁺-2Cl⁻ transport in the thick ascending loop of Henle. Thiazide diuretics and thiazide-like diuretics (chlorthalidone, indapamide) block the Na⁺-Cl⁻ cotransporter in the distal convoluted tubule. Spironolactone and eplerenone prevent aldosterone from activating the mineralocorticoid receptor, thereby inhibiting downstream activation of the epithelial sodium channel (ENaC), whereas triamterene and amiloride block ENaC directly; because less sodium is presented to the Na⁺,K⁺-ATPase on the vascular side of the collecting duct cells, less potassium is excreted in urine.

Clinical Use: Chlorthalidone rather than Hydrochlorothiazide

Even though HCTZ has enjoyed widespread use in clinical practice, chlorthalidone is the choice for practicing evidence-based medicine.

Greater effectiveness of chlorthalidone than HCTZ is strongly suggested by post hoc analysis of the MRFIT (Multiple Risk Factor Intervention Trial) data, which showed better outcomes with chlorthalidone,⁵⁸ by a network meta-analysis,⁵⁹ and by a small single-center ambulatory BP monitoring study showing a much longer duration of action.⁶⁰ A 25-mg dose of chlorthalidone is roughly equivalent in potency to a 50-mg dose of HCTZ. Loop diuretics are less effective BP-lowering agents and should be reserved for treating hypertension in the setting of advanced CKD (stage 3 or higher). Chlorthalidone may also be effective in patients with stage 3 CKD.

Diuretics enhance the potency of all other classes of antihypertensive agents. Thiazide and thiazide-like diuretics combine particularly well with ACEIs and ARBs, which blunt the reactive RAS activation and thus increase antihypertensive efficacy. Such low-dose combinations should also reduce dose-dependent diuretic side effects, but no formal dose-finding studies are available to clarify their use in clinical practice.

Side Effects

Thiazides and thiazide-like diuretics can aggravate glucose intolerance (particularly in higher doses and when used in combination with a beta blocker), cause hypokalemia and hypomagnesemia, precipitate gout, and elevate serum lipids with increased hepatic triglyceride content⁶¹; rarely, they cause photosensitive dermatitis. They are more likely than any other antihypertensive drugs to cause erectile dysfunction. These drugs are the most common cause of severe hyponatremia, especially in older adults.^{62,63} Although less well recognized than thiazide-induced hypokalemia, thiazide-induced hyponatremia is a common reason why some elderly hypertensive individuals simply cannot tolerate even low-dose thiazides. In hypertensive patients with CKD, high doses of loop diuretics may precipitate acute renal failure, especially if combined with high-dose ACEI or ARB therapy.

Add-On Drug Classes for Difficult Hypertension

Aldosterone Antagonists

Low-dose spironolactone (12.5 to 100 mg daily) is widely recommended as a highly effective add-on drug for difficult cases of hypertension.^{10,11,64} This recommendation is based on small single-site series and post hoc analysis of ASCOT, which used spironolactone (12.5 to 25 mg daily) as a fourth-line therapy. Eplerenone is a much more specific antagonist that avoids the infrequent sexual side effects of low-dose spironolactone (painful gynecomastia, erectile dysfunction, nonmenstrual uterine bleeding). Hyperkalemia must be avoided when using these agents in patients with kidney disease.

Beta-Adrenergic Blockers

Vasodilating beta blockers (labetalol, carvedilol, and nebivolol) are also highly effective add-on drugs for difficult hypertension; standard beta blockers (e.g., metoprolol, atenolol) are not.

Mechanism of Action

With the initiation of standard beta-blocking drug therapy, BP changes little at first because a compensatory increase in peripheral resistance offsets the fall in cardiac output. Over time, BP falls progressively as the peripheral vasculature relaxes. Thus the antihypertensive effect of beta blockade involves decreases in cardiac output (beta₁ receptors), renin release (beta₁ receptors), and norepinephrine release (prejunctional beta₂ receptors). The prototype beta blocker propranolol nonselectively blocks both beta₁ receptors and beta₂ receptors. Other standard beta blockers (metoprolol, atenolol, acebutolol, and bisoprolol) are relatively cardioselective. In low doses they exert a greater inhibitory effect on beta₁ receptors than on beta₂ receptors, but selectivity is lost at high doses. Vasodilating beta blockers such as labetalol or carvedilol also block alpha-adrenergic receptors, whereas nebivolol stimulates endogenous production of nitric oxide.

Clinical Use and Side Effects

Standard beta blockers have rather weak BP-lowering action. Several RCTs and meta-analyses have indicated that standard beta blockers such as atenolol and metoprolol provide stroke protection inferior to that with ACEIs, ARBs, CCBs, or diuretics. They provide modest protection against CV events but do not reduce all-cause mortality.⁶⁵ Standard beta blockers also increase the risk for diabetes, particularly when combined with a diuretic. Common side effects such as fatigability cause high discontinuation rates.⁵⁷ Beta blockers can impair cardiac conduction and precipitate acute bronchospasm in adults who had asthma in childhood. All beta-blocking drugs promote weight gain. Vasodilating beta blockers are much more potent antihypertensive agents and do not adversely affect glucose tolerance, but they have not undergone evaluation in large RCTs.⁶⁵ Data are also lacking on whether branded nebivolol is more cardioprotective than generic carvedilol, which is now included in \$4 per month formularies. Labetalol is effective treatment of hypertensive urgency but is too short acting to be recommended for chronic hypertension management.

Alpha-Adrenergic Blockers

Mechanism of Action

By blocking the interaction of norepinephrine on vascular alpha-adrenergic receptors, these drugs cause peripheral vasodilation, thereby lowering BP. By increasing blood flow in skeletal muscle, alpha blockers increase insulin sensitivity. By dilating urethral smooth muscle, they improve symptoms of prostatism. Prazosin, doxazosin, terazosin, and intravenous phentolamine selectively block alpha₁ adrenoceptors; phenoxybenzamine blocks both alpha₁ and alpha₂ receptors.

Clinical Use and Side Effects

Phenoxybenzamine remains the drug of choice for preoperative management of pheochromocytoma (see Chapter 81); after alpha blockade is achieved, a beta blocker should be added to block an otherwise excessive reflex tachycardia. Selective alpha₁-blocking drugs are not first-line agents and should not be used as monotherapy because their propensity to cause fluid retention can lead to tachyphylaxis and unmask or exacerbate heart failure. When used in a combination regimen that includes a diuretic, however, they are effective add-on therapy for difficult hypertension and are particularly useful in older men with prostatism. Although marketed specifically for prostatism and not as an antihypertensive agent, the selective alpha_{1A}-blocker tamsulosin lowers BP in some men.

Central Sympatholytics

Mechanism of Action

Stimulation of postsynaptic alpha₂-adrenergic receptors and imidazoline receptors in the central nervous system lowers central sympathetic outflow, whereas stimulation of presynaptic alpha₂ receptors causes feedback inhibition of norepinephrine release from peripheral sympathetic nerve terminals. These combined actions reduce adrenergic drive to the heart and peripheral circulation.

Clinical Use and Side Effects

The central sympatholytics are best reserved for short-term oral treatment of hypertensive urgency. They are potent antihypertensive agents that may be needed as add-on therapy for very difficult hypertension, but their troublesome central nervous system side effects reduce quality of life. To avoid rebound hypertension between doses, short-acting clonidine must be given every 6 to 8 hours or, whenever possible, discontinued via a gradual tapering schedule.⁶⁶ Rebound hypertension is less of a problem with longer-acting preparations (e.g., guanfacine, clonidine patch). Alpha-methyldopa remains useful for the management of hypertension in pregnancy but is no longer a first-line therapy.

Direct Vasodilators

Mechanism of Action

Minoxidil and hydralazine are potent hyperpolarizing arterial vasodilators that work by opening vascular ATP-sensitive K⁺ channels.

Clinical Use

By causing selective and rapid arterial dilation, both drugs induce profound reflex sympathetic activation and tachycardia. Hydralazine is useful for the treatment of preeclampsia. A combination of hydralazine plus nitrates is useful for the treatment of heart failure, specifically in non-Hispanic black patients, in whom hypertensive heart disease causes heart failure most commonly (see Chapters 25 and 27). Severe hypertension accompanying advanced CKD is the main indication for minoxidil, which must be combined with a beta blocker to prevent excessive reflex tachycardia and with a loop diuretic to prevent excessive fluid retention. Institution of hemodialysis is usually a more effective means of controlling hypertension in this setting.

PERCUTANEOUS INTERVENTIONS FOR MANAGEMENT OF BLOOD PRESSURE

Renal Denervation (also see Chapter 43)

Percutaneous catheter-based radiofrequency ablation of the renal nerves (referred to as renal denervation [RDN]) has already entered clinical practice in Europe and Asia as a novel treatment of drug-resistant hypertension, with clinical guidelines being published in 2013.⁶⁷ Based on impressive but unblinded data from phase I and phase II trials and office BP measurements, these guidelines will need to be reevaluated in light of a 2014 press release reporting that the blinded pivotal U.S. phase III trial (Symplicity HTN-3) did not reach its primary efficacy endpoint of a 15-mm Hg or greater reduction in office-based SBP in the RDN group versus the control group.⁶⁸ Further research will be needed to conclusively determine the relative merits of RDN versus optimal medication management, patient subsets who would be most likely and least likely to benefit, sustainability of the therapeutic benefit in view of possible reinnervation, and long-term safety.⁶⁹

Mechanism of Action (also See Chapter 43)

RDN therapy is derived from the premise that overactivity of the sympathetic nervous system contributes importantly to hypertension, especially severe drug-resistant hypertension. The targets of RDN are both the efferent postganglionic renal sympathetic nerves and the renal sensory (afferent) nerves. Overactivity of efferent renal nerves can cause renal vasoconstriction, stimulate renin release, and impair natriuresis (see Fig. 43-6). Overactivity of renal afferent nerves can trigger reflex efferent sympathetic nerve activation not only in the kidney but also in the heart (thereby promoting increased cardiac output, LVH, and atrial fibrillation), skeletal muscle (promoting increased vascular resistance and insulin resistance), and spleen (promoting T cell activation with secondary vascular inflammation and impaired endothelial function) (see Fig. 43-7).

Clinical Use

RDN is a percutaneous procedure with short recovery times and no significant systemic side effects (such as orthostatic hypotension or fatigue), the latter being a major advantage over central sympatholytic drugs. The Symplicity clinical trial program has demonstrated the short-term safety and efficacy of RDN for drug-resistant hypertension in phase I and II trials. Among patients with baseline SBP higher than 160 mm Hg despite treatment with an average of five antihypertensive drugs, substantial and progressively larger BP reductions were seen over 36 months of follow-up, with a goal SBP of lower than 140 mm Hg being achieved in 50% of patients.⁷⁰ Based on this evidence, the European Society of Cardiology recommended that “hypertensive patients are eligible for RDN if they have severe treatment-resistant hypertension defined by office SBP at least 160 mm Hg (≥150 mm Hg in type 2 diabetes) despite treatment with at least three antihypertensive drugs of different types in adequate doses, including one diuretic, which is equivalent to stage 2 or 3 hypertension.”⁶⁷ Further recommendations for screening are shown in Figure 44-2 and recommendations for eligibility in Table 44-8. Again, these

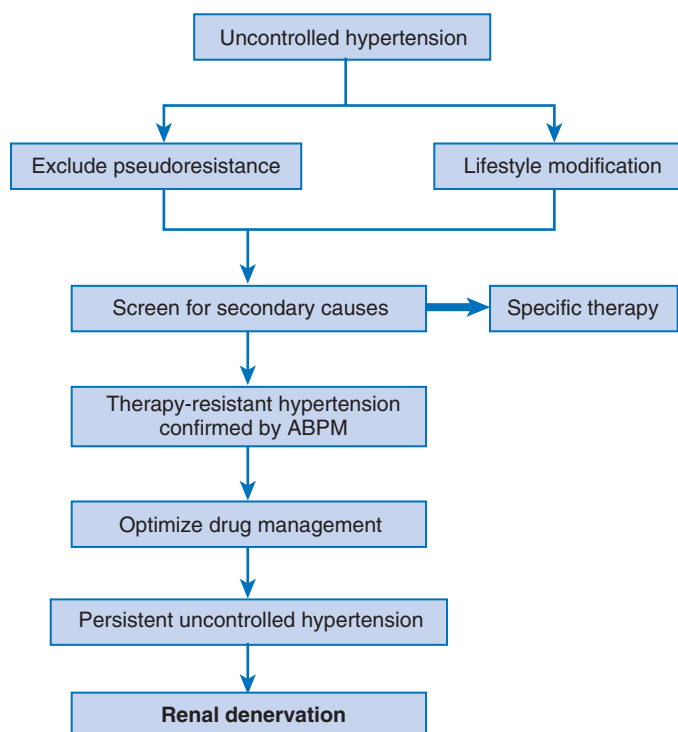

FIGURE 44-2 Recommended clinical protocol for selecting patients for RDN. ABPM = ambulatory blood pressure monitoring. (Modified from Mahfoud F, Luscher TF, Andersson B, et al: Expert consensus document from the European Society of Cardiology on catheter-based renal denervation. *Eur Heart J* 34:2149, 2013.)

recommendations will need to be reassessed when data from the Symplicity HTN-3 trial are published.

The trial's priority secondary endpoint is a reduction in 24-hour SBP as assessed by ambulatory BP monitoring in all patients.⁷¹ The latter will be most important because 6-month registry data from 47 patients who underwent RDN for clinical indications in 10 European hypertension centers of excellence showed that office BP fell by 18/7 mm Hg (from 175/98 to 158/91 mm Hg, $P = 0.01$) but 24-hour BP had a much smaller, more variable, and statistically nonsignificant change of $-6/-4$ mm Hg (from 157/92 mm Hg to 151/88 mm Hg, $P = 0.3$) (Fig. 44-3).⁷² These data underscore the pivotal importance of 24-hour ambulatory BP monitoring, which should become the primary outcome in evaluating the efficacy of RDN, baroreceptor pacing, or other sympatholytic device-based therapy for hypertension.

TABLE 44-8 Eligibility Criteria Before Considering Renal Denervation

Office SBP ≥ 160 mm Hg (≥ 150 mm Hg if type 2 diabetes)
>3 Antihypertensive drugs in adequate dosage and combination (including a diuretic)
Lifestyle modification
Exclusion of secondary hypertension
Exclusion of pseudoresistance using ABPM (average SBP ≥ 130 mm Hg or mean daytime SBP ≥ 135 mm Hg)
Preserved renal function (eGFR ≥ 45 mL/min/1.73 m ²)
Eligible renal arteries: no polar or accessory arteries, no renal artery stenosis, no previous revascularization

ABPM = ambulatory blood pressure monitor; eGFR = estimated glomerular filtration rate.

Modified from Mahfoud F, Luscher TF, Andersson B, et al: Expert consensus document from the European Society of Cardiology on catheter-based renal denervation. *Eur Heart J* 34:2149, 2013.

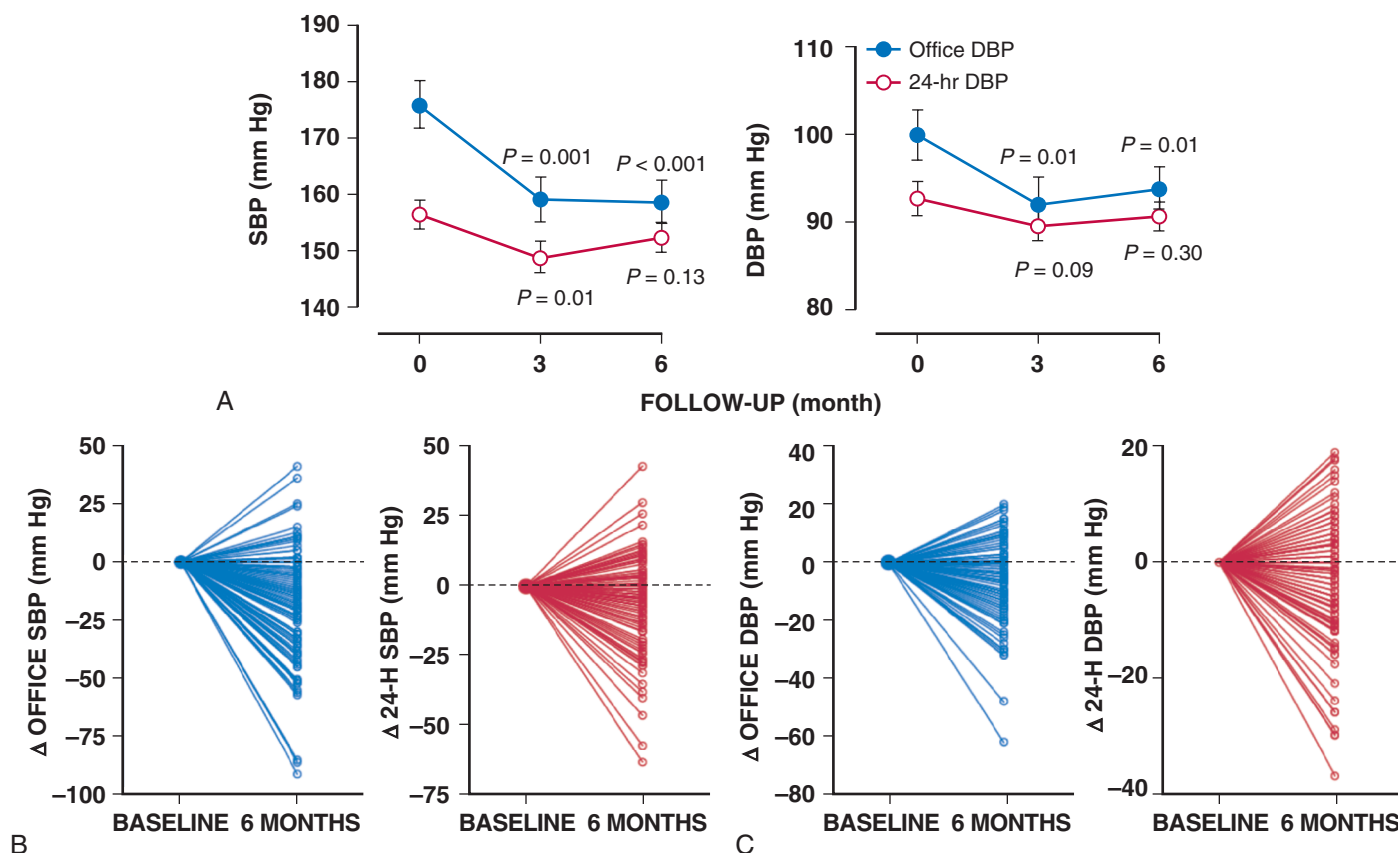

FIGURE 44-3 European registry data showing differential effects of renal denervation (RDN) on office and 24-hour ambulatory systolic blood pressure (SBP) and diastolic blood pressure (DBP) in patients who underwent RDN for resistant hypertension. Mean data (A) and patient-specific data on SBP (B) and DBP (C) are shown. (From Persu A, Jin Y, Azizi M, et al: Blood pressure changes after renal denervation at 10 European expert centers. *J Hum Hypertens* 28:150, 2014.)

Potential explanations for the negative Symplicity HTN-3 trial findings and the difficulty in showing an overall treatment benefit of RDN with 24-hour ambulatory BP monitoring could be the following:

- Patient selection. The sympathetic nerves will not be overactive in all patients with resistant hypertension. For example, renal norepinephrine spillover is most consistently elevated in young hypertensive patients (20 to 39 years of age) but is indistinguishable from normotensive levels in older hypertensive patients (60 to 79 years of age).⁷³ RDN may have little effect if the renal sympathetic nerves are not overactive.
- Incomplete denervation. There is no verification procedure to prove the completeness of RDN at the time of the procedure. Because the catheter is in the lumen of the renal artery, the thermal energy produced has to cross the arterial wall to reach the nerves located in the adventitia. Incomplete denervation is of particular concern with renal afferents; in animal studies, 100% destruction of afferents is needed to attenuate a BP-raising reflex, but almost complete deafferentation has practically no effect.
- Trial design issues. Medication noncompliance may be a confounder because patients enrolled in RDN trials were receiving an average of five BP medications.

Side Effects

Periprocedural events requiring treatment are rare but include femoral artery pseudoaneurysm and renal artery dissection. Isolated case reports have described renal artery stenosis occurring 1 year later at the site of denervation.⁷⁴ Three-year follow-up data from Symplicity HTN-1 showed that RDN does not prevent a decline in the estimated glomerular filtration rate (eGFR),⁷⁰ but without a control group, we do not know whether this decline in eGFR is less or greater than what would occur in severely hypertensive individuals without RDN.

Carotid Baroreceptor Activation

An implantable carotid baroreceptor pacemaker system was described in [Chapter 43](#). This strategy also holds exciting promise for the management of difficult hypertension. Although the U.S.

pivotal trial with the prototype Rheos system did not meet its primary endpoint,⁷⁵ a second U.S. pivotal trial with an improved second-generation system (Barostim neo) is under way ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01679132); identifier, NCT01679132).

EVIDENCE-BASED APPROACH TO MANAGEMENT OF HIGH BLOOD PRESSURE

Despite the enormous evidence base for medical treatment of hypertension, important gaps remain. Most RCTs on hypertension have enrolled high-risk patients with a mean age of 67 years, stage 2 hypertension (baseline SBP ≥ 160 mm Hg), and multiple CV risk factors and comorbid conditions to select a population with sufficient events so that a primary endpoint could be reached in 5 years or less. Several trials have been halted early on recommendation of the data safety monitoring board. Thus this large body of evidence does not apply directly to the treatment of patients younger than 50 years or those with stage 1 hypertension, prehypertension, or lower CV risk profiles. On the other hand, metaregression analysis indicates that BP-lowering regimens reduce CV events regardless of the pretreatment BP level (see [Fig. 44-1](#)).⁴⁵ Moreover, the reported short-term reductions in risk underestimate the lifetime benefit accrued over decades of reduced high BP.

The large number of RCTs on hypertension (mainly since 1990) organized by patient population CV risk gradient are listed in [Table 44-9](#). Most were designed as monotherapy trials to compare a single active drug versus placebo or a newer drug versus an older drug (active comparator). Yet RCTs have shown that most hypertensive patients will require at least two and often three or more medications of different drug classes plus lifestyle modification to control their hypertension.⁸ A meta-analysis of more than 40 RCTs showed that combining any two drugs at their starting doses is five times more effective in lowering BP than doubling the dose of any single drug.⁷⁶ Combination drug therapy has synergistic effects on BP and permits the use of lower doses to minimize dose-dependent side effects. Thus the key question is not about the single best drug to initiate medication management but rather the most effective drug combinations for

TABLE 44-9 Hypertension Randomized Trials Organized by Risk Gradient

long-term management of hypertension. Although only a few recent trials specifically tested drug combinations, most patients in the trials included in Table 44-9 received the prespecified step 2 drugs and/or step 3 drugs listed.

A key unanswered question is the optimal target level of BP to be achieved by treatment. The 2003 JNC 7 report⁷⁷ recommended a BP treatment target of below 140/90 mm Hg for most hypertensive patients

but a more stringent target of below 130/80 mm Hg for those with diabetes mellitus or CKD because these comorbid conditions are associated with very high CV risk. The 2008 AHA/ACC position statement on treatment of hypertension in patients with coronary disease⁷⁸ expanded the below 130/80-mm Hg target high-risk group to include most hypertensive patients treated by cardiologists (e.g., those with known or suspected coronary disease or peripheral arterial disease or

any patient requiring primary prevention for high global CV risk). Both the JNC 7 and AHA/ACC recommendations for the below 130/80-mm Hg treatment target were based largely on expert opinion.

Furthermore, all major RCTs to date have been based on conventional office BP, which often leads to overtreatment or undertreatment of hypertension in everyday clinical practice. This consideration has particular importance in elderly persons and those with diabetes or CKD (see below).

This section reviews the evidence keyed to Table 44-9 to address two questions: (1) how far to lower BP and (2) which drugs for which patients?

Patients with Prehypertension

Prehypertension is considered a precursor of stage 1 hypertension and a predictor of excessive CV risk. The outcomes of TROPHY (Trial of Preventing Hypertension) suggest that pharmacologic treatment of prehypertension with an ARB—when superimposed on lifestyle coaching—can postpone stage 1 hypertension.⁷⁹

Hypertensive Patients in General

In many of the general hypertension trials listed in Table 44-9 and shown in Figure 44-4A, the active treatment group achieved a final mean SBP below 140 but always above 130 mm Hg. Metaregression analysis suggests—but does not prove—that further lowering of BP will provide additional CV protection even when the baseline BP is lower than 140/90 mm Hg (see Fig. 44-1).⁴⁵ The ongoing National Institutes of Health (NIH)-funded SPRINT (Systolic Blood Pressure Intervention Trial) is testing this possibility prospectively (ClinicalTrials.gov; identifier, NCT01206062). In RCTs, group differences in CV event rates are largely explained by small group differences in reduction of SBP (hemodynamic load) rather than drug class, with three caveats. First, beta blockers provide less stroke protection and CCBs more stroke protection than do other drugs. Second, the combination of an ACEI/CCB (amlodipine) may be an excellent option to initiate medication management for hypertension because it prevented more CV events than did the beta blocker/thiazide diuretic combination in ASCOT⁴⁷ and the ACEI/HCTZ combination in the ACCOMPLISH trial (Fig. 44-5).⁴⁸ CCBs are better tolerated and avoid the metabolic cost of the thiazides, including hyponatremia, hypokalemia, aggravation of glucose intolerance, increased hepatic triglyceride content, and gout. Yet the 2013 scientific advisory from the AHA/ACC/CDC⁷ still emphasizes diuretic-based therapy in the belief that the totality of the evidence is greater than with any other drug class; in the ACCOMPLISH trial, the choice of low-dose HCTZ rather than the more potent chlorthalidone may have blunted the reduction in CV risk in the ACEI/diuretic arm. Third, ONTARGET showed that “dual RAS blockade” is dangerous as combined treatment with both an ACEI and an ARB (ramipril plus telmisartan), has no advantage on CV outcomes over monotherapy with either drug alone,⁴⁹ but results in much more symptomatic hypotension and more renal impairment (Fig. 44-6).⁵¹

Systolic Hypertension in Elderly Patients

Most hypertensive patients are older than 65 years, and most have isolated systolic hypertension (see Chapter 43). Six placebo-controlled trials have provided unequivocal proof that any BP-lowering regimen reduces CV events in elderly hypertensive patients (see Table 44-9 and Fig. 44-4B). The mean age of the patients at baseline ranged from 70 to 76 years except for HYVET (Hypertension in the Very Elderly Trial), in which all patients were 80 years or older.⁸⁰ The benefits of treatment include fewer coronary events, strokes, heart failure events, and deaths. In metaregression analysis, antihypertensive drugs were found to be just as effective in preventing CV events in patients older or younger than 65 years.⁸¹ However, the intensity of the BP reduction in elderly patients must be weighed against increased risk for hypotension, which can precipitate falls and ischemic events. The lowest mean SBP reached in these trials was 144 to 145 mm Hg, including HYVET.⁸⁰ These trials support the key point that even modest reduction in SBP can confer great benefit in hypertensive elderly patients.

FIGURE 44-4 Initial and final average SBP in the experimental group of randomized control trials of hypertensive patients in general (A) and elderly hypertensive patients (B). The LIFE trial enrolled only patients with electrocardiographic LVH; INVEST enrolled only patients with documented coronary artery disease. See Table 44-9 for further details.

Taken together, the available evidence in robust elderly patients supports an office SBP treatment target of below 150 mm Hg. Whether there are additional benefits in reducing office SBP in active, otherwise healthy elderly patients to below 140 mm Hg is being tested in SPRINT.

The 2011 U.K. guidelines from the National Institute of Clinical Excellence (NICE) and the 2013 European Society of Hypertension (ESH)/European Society of Cardiology (ESC) guidelines place far greater emphasis than U.S. guidelines do on home and ambulatory BP monitoring for clinical decision making.^{10,11,82} Based on registry data from the 11-country International Database on Ambulatory BP in Relation to Cardiovascular Outcomes (IDACO), ambulatory and home BP monitoring should be routine in hypertensive elderly individuals; white coat (office only) hypertension and masked (out-of-office only) hypertension are so common in older adults that conventional office BP readings alone will promote either overtreatment or undertreatment of hypertension in three of four patients.⁸³

FIGURE 44-5 Major outcomes of the ACCOMPLISH trial. The SBP and DBP levels achieved and corresponding Kaplan-Meier analysis of the primary outcome (death from CV causes, nonfatal myocardial infarction, nonfatal stroke, hospitalization for angina, resuscitation after sudden cardiac arrest, and coronary revascularization) are shown for patients randomly assigned to benazepril plus amlodipine or benazepril plus HCTZ. (From Jamerson K, Weber MA, Bakris GL, et al: Benazepril plus amlodipine or hydrochlorothiazide for hypertension in high-risk patients. *N Engl J Med* 359:2417, 2008.)

FIGURE 44-6 Major cardiovascular and renal outcomes of ONTARGET. **Left panel**, The cumulative hazard ratio for the primary composite CV outcome (death from CV causes, myocardial infarction, stroke, or hospitalization for heart failure) was indistinguishable in patients randomly assigned to telmisartan alone (T), ramipril alone (R), or combination treatment with telmisartan plus ramipril (R + T). **Right panel**, The decrease in eGFR was best with ramipril alone, intermediate with telmisartan alone, and worst when telmisartan and ramipril were combined. (Left panel, From Yusuf S, Teo KK, Pogue J, et al: Telmisartan, ramipril, or both in patients at high risk for vascular events. *N Engl J Med* 358:1547, 2008; Right panel, from Mann JF, Schmieder RE, McQueen M, et al: Renal outcomes with telmisartan, ramipril, or both, in people at high vascular risk [the ONTARGET study]: A multicentre, randomised, double-blind, controlled trial. *Lancet* 372:547, 2008.)

Moreover, ambulatory monitoring is key to detecting *postprandial hypotension* and *orthostatic hypotension*, which are common in hypertensive elderly patients (Fig. 44-7). Management of postprandial hypotension is challenging. Useful strategies include frequent small low-carbohydrate meals, caffeine with meals, and liberalized salt intake. If these non-drug-related strategies prove insufficient, fludrocortisone (Florinef) can be added but often causes or worsens supine hypertension, which can be managed by elevation of the head of the bed (with 6-inch cinder blocks to produce a 30-degree head-up tilt) and a low-dose short-acting ARB (losartan, 25 to 50 mg) at bedtime.⁸⁴ The evidence is insufficient to recommend

the use of midodrine, an alpha-adrenergic agonist, for orthostatic hypotension.⁸⁵

The ACC Foundation (ACCF)/AHA 2011 expert consensus document on hypertension in older adults recommends initiating antihypertensive therapy with any one of the three first-line drugs, CCB, ACEI or ARB, or thiazide, while placing the most emphasis on thiazides.⁴ Most patients will require combination therapy with two or three drugs, so it is important to titrate more slowly in the elderly and to check frequently for orthostatic hypotension and adverse drug reactions—especially thiazide-induced hyponatremia⁶²—which are more common. On average, elderly patients take more than six

FIGURE 44-7 Postprandial and orthostatic hypotension demonstrated by ambulatory BP monitoring. The 24-hour ambulatory BP recording is from a frail 70-year-old woman referred for evaluation of labile hypertension and dizziness. Red arrows show repeated episodes of postprandial hypertension and one episode of orthostatic hypotension when the patient walked to the bathroom 90 minutes after going to sleep. White coat reactions also seen when the patient came to the clinic to have the monitor placed and then to have it removed. bpm = beats/min; HTN = hypertension. (Courtesy Ronald G. Victor, MD, Hypertension Center, Cedars-Sinai Heart Institute.)

prescription drugs, so polypharmacy, noncompliance, and potential drug interactions are key concerns. Regimens with combination drugs and agents or formulations that permit less frequent dosing can simplify the treatment program and promote persistence. Therapy should be individualized and be based more on the person's overall health than on chronologic age (see [Practical Clinical Approach to the Evaluation and Management of Ambulatory Hypertensive Patients](#) later in this chapter).

Hypertension with Left Ventricular Hypertrophy

More than a third of hypertensive patients have electrocardiographically apparent LVH by the time of diagnosis, a finding that places them at increased risk for hypertensive complications, including heart failure, stroke, and atrial fibrillation. The LIFE (Losartan Intervention for Endpoint Reduction in Hypertension) trial exclusively enrolled patients with electrocardiographically confirmed LVH and showed superiority of an ARB/HCTZ-based regimen over a beta blocker/HCTZ-based regimen for regression of LVH and prevention of CV events, especially stroke.⁸⁶ Subsequent meta-analyses have confirmed the superiority of ARBs for regression of LVH.⁸⁷ Beta blockers are the least effective; alpha- rather than beta-adrenergic receptors mediate the trophic effect of catecholamines on cardiac myocytes.

Hypertension in Patients with Diabetes Mellitus

Patients with diabetes mellitus commonly have hypertension. In the ADVANCE (Action in Diabetes and Vascular disease: Preterax and Diamicon MR Controlled Evaluation) trial, the relative risk for CV

death fell by 18% when BP was reduced from 144/81 mm Hg to 139/79 mm Hg with a fixed combination of perindopril and indapamide.⁸⁸ The recent ACCORD (Action to Control Cardiovascular Risk in Diabetes) study showed no difference in coronary events in patients with diabetes whose SBP was reduced to 119 mm Hg versus 133 mm Hg but did show a greater reduction in stroke ([Fig. 44-8](#)). The ACCORD study may have lacked power to establish such a difference because of the very low number of CV events that occurred in the diabetic study patients, most of whom received treatment with statins and other CV risk reduction measures. Moreover, reliance on clinic BP presents particular problems in trials of diabetic patients because of the prevalence of masked hypertension,⁸⁹ an issue not assessed in the ACCORD trial. Two meta-analyses also concluded that in patients with diabetes, protection from stroke but not myocardial infarction increases with the magnitude of reduction in BP.^{90,91} Diabetic nephropathy is discussed below. There is no direct evidence that the three first-line BP drug classes should be any different in terms of treating patients with or without diabetes, although diuretics can aggravate glucose intolerance. If additional drugs are needed to control hypertension, vasodilating beta blockers do not aggravate glucose tolerance in patients with type 2 diabetes.⁹²

ALTITUDE (Aliskiren Trial in Type 2 Diabetes Using Cardiorenal Endpoints) showed that addition of the DRI aliskiren to background therapy with an ACEI or ARB increases the incidence of

hyperkalemia and hypotension while producing no added CV benefit; these results led to a black box FDA warning against this form of dual RAS blockade.⁵⁵

Hypertension in Patients with Diabetic Nephropathy

Diabetic nephropathy is accompanied by proteinuria, loss of renal autoregulation, hypertension, progression to end-stage renal disease, and a high incidence of CV events. In RCTs, the addition of an ARB to background antihypertensive therapy was found to slow progression of nephropathy in patients with type 2 diabetes, whereas amlodipine did not.^{93,94} Thus type 2 diabetes with nephropathy is an indication for an ARB, even though the trials were not powered to determine whether CV protection is also afforded. There is evidence to recommend an office BP goal of 140/90 mm Hg or lower for patients with type 2 diabetic nephropathy ([Table 44-9](#)). The 2013 Kidney Disease Improving Global Outcomes (KDIGO) guideline⁹⁵ recommends a stretch goal of less than 130/80 mm Hg in those with significant proteinuria (urine-to-plasma albumin-to-creatinine ratio of ≥ 30 mg/g, a figure corresponding to ≥ 30 mg of urinary albumin excretion in 24 hours), which is the case in most patients.

Hypertension in Patients with Nondiabetic Chronic Kidney Disease

The vast majority of patients with nondiabetic CKD have hypertension. Control of hypertension in patients with CKD has two goals: (1) slowing further deterioration in renal function and (2) preventing CV events, which are the main cause of death. In AASK, the ACEI ramipril was more renoprotective than either amlodipine or metoprolol in

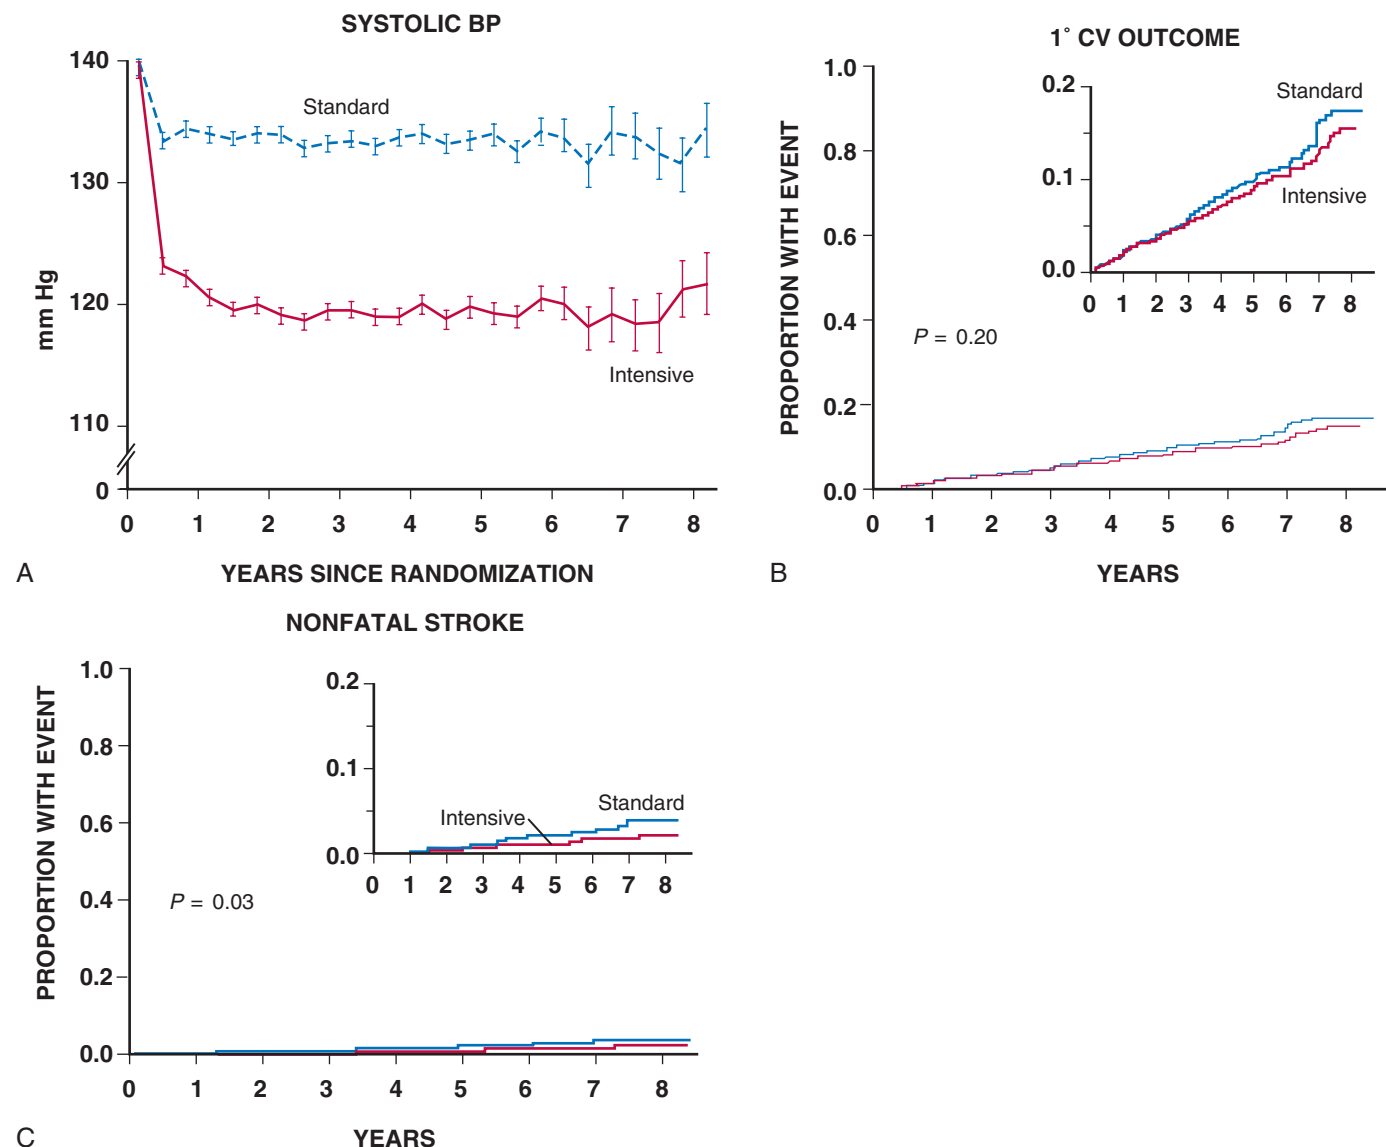

FIGURE 44-8 Major outcomes of the ACCORD study. SBP levels achieved with standard and intensive treatment are shown along with corresponding Kaplan-Meier analyses for the primary outcome (nonfatal myocardial infarction, nonfatal stroke, or death from CV causes) and for nonfatal stroke. The insets show close-up versions of the graphs in each panel. (From ACCORD Study Group, Cushman WC, Evans GW, Byington RP, et al: Effects of intensive blood-pressure control in type 2 diabetes mellitus. *N Engl J Med* 362:1575, 2010.)

black patients with baseline proteinuria.⁹⁶ Long-term follow-up of the AASK participants and a recent meta-analysis have indicated that intensive reduction of SBP to below 130 mm Hg rather than a less intense goal of 140 mm Hg slows progression of renal disease only in patients with baseline proteinuria.^{97,98} These trials lacked power to assess CV outcomes. Thus the 2013 KDIGO guideline recommends a goal office BP of lower than 140/90 mm Hg for patients with nondiabetic nonproteinuric CKD and a stretch goal of less than 130/80 mm Hg with an ACEI- or ARB-based regimen for those with proteinuria.

Reduction of Blood Pressure for Secondary Prevention of Coronary Events and the J Curve Hypothesis

There is insufficient evidence from RCTs to recommend an optimal BP treatment target for secondary prevention of coronary events. The 2011 ACCF/AHA/AMA Physician Consortium for Performance Improvement (PCPI) report on performance measures for adults with coronary disease and hypertension recommended (1) a goal office BP lower than 140/90 mm Hg and (2) prescription of two or more BP medications if office BP is not at goal.⁵ Beta blockers and CCBs are both antianginal and antihypertensive. Debate continues over the

practical importance of the *J-curve hypothesis*, which holds that overtreatment of DBP impairs coronary perfusion and thus may worsen myocardial ischemia and provoke coronary events, especially in patients with coronary artery stenoses. Yet no prospective data from RCTs have defined a critical lower limit of on-treatment BP that increases the risk for ischemic events. Retrospective analysis of INVEST (International Verapamil Trandolapril Trial) and other data sets are limited by dwindling sample size at critically important levels of DBP below 70 to 80 mm Hg and by potential confounding from reverse causality.⁹⁹ For example, a DBP of 60 mm Hg may not be the cause of adverse CV outcomes in retrospective studies but rather could result from patients having a terminal illness or underlying isolated systolic hypertension, which itself is a potent CV risk factor.

Reduction of Blood Pressure for Secondary Prevention of Stroke

Stroke survivors are at high risk for recurrent stroke and thus further disability and death. Reduction in SBP by more than 10 mm Hg can reduce these risks.¹⁰⁰ In the PROGRESS (Perindopril Protection

Against Recurrent Stroke Study) trial of patients who had survived ischemic or hemorrhagic stroke, outpatient reduction of SBP by 12 mm Hg to a value of 135 mm Hg with an ACEI/diuretic (perindopril/indapamide) combination reduced the relative risk for recurrent ischemic stroke by 36% and that for recurrent hemorrhagic stroke by 76% in comparison to placebo, but a smaller reduction in BP of just 5 mm Hg with perindopril monotherapy showed no stroke protection.¹⁰¹ Similarly, in the subsequent PROFESS (Prevention Regimen for Effectively Avoiding Second Strokes) trial of patients with ischemic stroke, no statistical benefit was found when SBP was reduced by only 4 mm Hg with ARB (telmisartan) monotherapy versus placebo.¹⁰² Emergency management of BP during acute stroke is discussed later in the chapter (Management of Hypertensive Crises).

SPECIAL CONSIDERATIONS IN MANAGEMENT

Special Populations

Hypertension in Non-Hispanic Black Patients

Hypertension is particularly devastating in non-Hispanic black adults, who have a higher prevalence of hypertension than other groups do and higher rates of hypertensive complications and death (see Chapter 43). Black hypertensive patients were exclusively recruited in AASK (discussed above) and, by design, accounted for 25% of ALLHAT participants but otherwise have been underrepresented in most RCTs of hypertension. Among the subset of black patients in ALLHAT, the ACEI provided less BP reduction and thus less stroke protection than either the diuretic or the CCB did. In clinical practice, achieving BP targets and thus CV protection requires combining an ACEI with either a CCB or a diuretic, or both. In the absence of available evidence from RCTs, expert opinions vary whether additional CV protection would be afforded by setting lower than usual office SBP targets (to <135 or even <130 mm Hg) for black patients.^{6,103} A higher prevalence of nocturnal hypertension in black persons⁶ argues for greater use of ambulatory BP monitoring in clinical practice. A RCT showed that a barber shop-based BP monitoring and physician referral program can improve control of hypertension in black men.¹⁰⁴

Hypertensive Disorders in Women (See Chapter 77)

Oral Contraceptives and Hormonal Replacement Therapy

Estrogen-containing oral contraceptives (OCs) occasionally cause hypertension, which is often mild. BP normalizes within 6 months of stopping OC therapy in 50% of patients. The hypertensive mechanism involves both RAS activation and volume expansion. Use of OCs should be restricted in women older than 35 years or those who are obese or have preexisting hypertension. BP should be monitored closely with initiation of OCs; if BP rises into the prehypertensive range, an alternative contraceptive method should be offered. If OCs remains the only acceptable contraceptive method, drug therapy can reduce the elevated BP. Unlike OCs, hormonal replacement therapy does not appear to elevate BP.

Hypertension in Pregnancy (See Chapter 78)

Hypertensive disorders in pregnancy are a major cause of maternal-fetal morbidity and mortality, including a 25% incidence of preterm births. Current guidelines are provided by the 2013 executive summary of the American College of Obstetricians and Gynecologists.¹⁰⁵ Four categories of hypertension in pregnancy are recognized: (1) preeclampsia, (2) chronic hypertension, (3) chronic hypertension with superimposed preeclampsia, and (4) gestational hypertension. Preeclampsia is a severe progressive multisystem disorder diagnosed by hypertension accompanied by any one of the following: proteinuria, BP of 160/110 mm Hg or higher despite bed rest, thrombocytopenia, impaired liver function, progressive renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbance (see Table 44-7). Preeclampsia causes 15% of maternal deaths. Gestational hypertension is BP elevation after 20 weeks of gestation in the absence of the

TABLE 44-10 Diagnostic Criteria for Preeclampsia

Blood pressure	≥140/90 mm Hg on 2 occasions at least 4 hr apart after 20 wk of gestation in a woman with a previously normal pregnancy ≥160/110 mm Hg; hypertension can be confirmed within a short interval (minutes) to facilitate timely antihypertensive therapy
and	
Proteinuria	≥300 mg per 24-hour urine collection or Protein-creatinine ratio ≥ 0.3
or in the absence of proteinuria, new-onset hypertension with the new onset of any of the following:	
Thrombocytopenia	Platelet count < 100,000/mL
Renal insufficiency	Serum creatinine > 1.1 mg/dL or doubling of serum creatinine in the absence of other renal disease
Impaired liver function	Serum liver transaminases elevated twice normal
Pulmonary edema	
Cerebral or visual symptoms	

Modified from Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. Obstet Gynecol 122:1122, 2013.

additional systemic features listed in Table 44-10. Chronic hypertension is that predating pregnancy. In all cases, ambulatory BP monitoring is very useful and was recently reported to be superior to conventional office measurement of BP for prediction of outcomes.^{82,106} Although the pathogenesis of gestational hypertension/preeclampsia remains enigmatic, risk factors include maternal age younger than 20 or older than 35 years, positive personal or family history of gestational hypertension, preexisting hypertension, obesity, diabetes, and antiphospholipid antibodies. Preeclampsia is a risk factor for peripartum cardiomyopathy, which may share common causative factors.¹⁰⁷

Low-dose aspirin (60 to 80 mg daily beginning in the first trimester) is recommended as being slightly effective in reducing the risk for preeclampsia in women with a past history of preeclampsia leading to preterm delivery or multiple episodes of preeclampsia. Women with gestational hypertension or chronic hypertension should be monitored closely for the development of preeclampsia with serial measurements of BP twice weekly and weekly assessment of platelet counts, liver enzymes, and proteinuria. Weight loss and salt restriction are not recommended. Antihypertensive medication is not recommended for uncomplicated stage 1 gestational hypertension and is reserved only for stage 2 hypertension (BP >160/110 mm Hg). Drug treatment of mild maternal hypertension does not improve perinatal outcome and may be associated with fetal growth retardation. Definitive cure of preeclampsia is termination of pregnancy. The decision regarding premature termination of pregnancy is based on evidence of fetal growth restriction, evidence of impaired placental blood flow by umbilical artery Doppler assessment, and the condition of the mother. Intravenous magnesium sulfate is not a reliable antihypertensive agent but is very effective in treating or preventing seizures in the setting of eclampsia or severe preeclampsia. Intravenous labetalol has replaced hydralazine as the drug of choice for treating severe preeclampsia/eclampsia. When compared with hydralazine, labetalol carries a lower risk for overshoot hypotension, which can impair fetal blood flow, and does not cause reflex tachycardia. Beyond delay of pregnancy until after the teenage years and better prenatal care, the only other effective strategy to prevent preeclampsia is the use of low-dose aspirin. The only cure for preeclampsia is delivery, which removes the diseased placenta. To achieve this apparently simple end, the clinician must detect the often-symptomless prodromal

condition by screening all pregnant women, admitting those with advanced preeclampsia to the hospital to keep track of an unpredictable situation, and timing preemptive delivery to maximize safety of the mother and baby.

For pregnant women with stage 2 hypertension but without severe preeclampsia/eclampsia, oral drug therapy should be initiated with any one of three preferred drugs: labetalol, nifedipine, or methyldopa. Despite being the conventional drug of choice, methyldopa is poorly tolerated and, if used after delivery, may cause postpartum depression. All RAS inhibitors must be discontinued. Delivery soon after maternal stabilization is recommended irrespective of gestational age for women with superimposed preeclampsia and any of the following: uncontrollable severe hypertension, eclampsia, pulmonary edema, abruptio placentae, disseminated intravascular coagulation, or fetal distress. Intravenous nitroglycerin is the treatment of choice when pulmonary edema accompanies preeclampsia, a main cause of maternal death. Preeclampsia can start in the early postpartum period. Preeclampsia constitutes an important major CV risk factor for later life. Women with preeclampsia causing preterm delivery have an almost 10-fold increased risk for CV disease in later life and thus require exquisite global risk factor modification.

For women with preeclampsia or even gestational hypertension, BP should be monitored closely in the hospital for 72 hours postpartum and again on outpatient basis 7 to 10 days after delivery. All BP drugs are secreted into human breast milk, but at low concentrations, except for high concentrations with propranolol and nifedipine, which should therefore be avoided.

Pediatric and Adolescent Hypertension

Historically, childhood hypertension was a rare occurrence caused mainly by parenchymal renal disease. The worldwide childhood obesity epidemic has, however, increased the prevalence of primary juvenile hypertension, which has now become one of the most common health conditions in the young.¹⁰⁸ Pediatric hypertension is defined as SBP or DBP higher than the 95th percentile for age, sex, and height according to normative data. The prevalence of hypertension is now 4% and that of prehypertension is 10% in U.S. children. The frequency of primary (largely obesity-related) hypertension in pediatric referral series has risen steadily from 15% in 1988 to 50% to 90% in 2006 to 2010.¹⁰⁸ College football players have a disproportionate prevalence of hypertension when compared with collegiate athletes in other sports; in one cross-sectional series, 19% of college football players had hypertension and 62% had prehypertension, which is partially explained by a high BMI.¹⁰⁹ In a longitudinal series, a single season of freshman collegiate football consistently caused increases in SBP and DBP associated with increased concentric left ventricular mass; these increases were greatest in linemen, who are heavier and gain more weight than those who are not linemen.¹¹⁰

Ambulatory BP monitoring is the method of choice for confirming the diagnosis of pediatric or adolescent hypertension, but it is underused.¹¹¹ The AHA provides guidelines for interpreting pediatric ambulatory BP monitoring values.¹¹² The initial evaluation should include an echocardiogram for detection of LVH, as well as urine microalbumin, serum creatinine, and urinalysis to test for renal parenchymal injury. Glomerulonephritis and reflux nephropathy can also be associated with pediatric hypertension. A history of recurrent urinary tract infections may indicate reflux nephropathy, a condition that can lead to renal scarring (suggested by renal asymmetry). Consultation with a pediatric nephrologist is indicated to consider reimplantation of the ureters. Renovascular hypertension occurs in almost 10% of hypertensive pediatric patients. Coarctation of the aorta, the most common cause of hypertension in infants, responds well to stenting.¹¹³ Rare causes of secondary pediatric hypertension are syndromic pheochromocytoma/paraganglioma, monogenic disorders (see Chapter 43), and congenital adrenal hyperplasia caused by deficiency of either 11-beta-hydroxylase or 17-alpha-hydroxylase. ACEIs are commonly used to treat primary pediatric hypertension and secondary hypertension caused by renal parenchymal disease; CCBs should be added as a second drug if needed.¹¹⁴

Hypertension and Erectile Dysfunction

Two thirds of men with hypertension have erectile dysfunction.¹¹⁵ TOMHS (Treatment of Mild Hypertension Study) is the only RCT on hypertension to include erectile dysfunction as a prespecified patient-reported outcome.¹¹⁶ Among men with a mean age of 50 years and previously untreated hypertension, most of the erectile dysfunction preceded initiation of antihypertensive medication and was related both to age and to baseline SBP. After men were randomly assigned to monotherapy with one of five main classes of BP medication or placebo, chlorthalidone was the only drug that increased incident erectile dysfunction more than placebo did. Overall, phosphodiesterase 5 inhibitors have had a very good safety record in treating erectile dysfunction, even in men with high CV risk, but they should be avoided in those taking nitrates or alpha blockers to prevent hypotension.

Hypertension and Hypertrophic Cardiomyopathy

Hypertension is at least as prevalent in patients with hypertrophic cardiomyopathy as in the general population. Management of hypertension in these patients presents challenges because all the first-line antihypertensive drugs—dihydropyridine CCBs, RAS blockers, and thiazides—can exacerbate outflow tract obstruction and are potentially harmful. Hypertension is best treated with a beta blocker and/or verapamil or diltiazem, with central sympatholytics and very low-dose thiazide being reserved as add-on drugs.¹¹⁷

Resistant Hypertension

Resistant hypertension—defined as high BP uncontrolled with three or controlled with at least four antihypertensive drugs (including a diuretic)—is associated with a higher prevalence of secondary hypertension and worse CV and renal outcomes. With aging of the population, the prevalence of resistant hypertension is increasing and is estimated to affect 13% to 20% of the adult U.S. population.¹¹⁸ More than half of these patients will have pseudoresistant hypertension from improper BP measurement technique, white coat reactions, medication noncompliance, pressor substances (e.g., NSAIDs, excessive alcohol, psychiatric drugs), or an inadequate BP regimen (Table 44-11). Common correctable issues include clonidine rebound (especially with as-needed dosing) and inadequate diuretic therapy: inappropriate use of a loop diuretic in a patient with normal renal function, infrequent dosing with a short-acting loop diuretic (e.g., once-daily furosemide), or a low-dose thiazide in a patient with impaired renal function.

Truly drug-resistant patients are a special high-risk population because of their severe hypertension along with target-organ damage and concomitant CV risk factors. Patients should be screened for secondary hypertension, especially CKD, obstructive sleep apnea, primary aldosteronism, and pheochromocytoma. In the absence of an identifiable cause of the hypertension, a mineralocorticoid receptor antagonist or a vasodilating beta blocker can serve as highly effective add-on therapies. Low-dose eplerenone or spironolactone can be remarkably effective for resistant hypertension—even when serum aldosterone is within the normal range. RDN is an exciting new option that was discussed earlier.

TABLE 44-11 Causes of Resistant Hypertension

Pseudoresistant Hypertension
Inadequate blood pressure regimen
Pressor substances
White coat reaction
Medication nonadherence
Improper blood pressure measurement
Truly Resistant Hypertension
Chronic kidney disease
Primary aldosteronism
Other secondary hypertension
Difficult primary hypertension

Perioperative Management of High Blood Pressure (See Chapter 80)

Preexisting hypertension should be well controlled before elective surgery. Preoperative correction of diuretic-induced potassium depletion requires particular attention. Antihypertensive agents should be taken the morning of surgery, particularly to avoid withdrawal from beta blockers or clonidine. Some surgeons prefer to withhold ACEIs and ARBs before cardiac surgery to prevent postoperative vasodilation and hypotension, but little evidence supports this practice. Fortunately, intravenous formulations of most agents are available if oral intake is not possible; labetalol and nicardipine have particular usefulness in this regard. Hypertension may appear or worsen in the perioperative period, perhaps more commonly with cardiac than with non-cardiac-related surgery. Hypertension is of particular concern after heart transplantation and develops for a variety of reasons, including immunosuppression with calcineurin inhibitors (cyclosporine and tacrolimus) and possibly cardiac denervation; treatment includes dihydropyridine CCBs, diuretics, and central sympatholytics.

MANAGEMENT OF HYPERTENSIVE CRISES

Definitions

Hypertensive crises are a heterogeneous group of hypertensive disorders characterized by severe hypertension and acute target-organ damage to the brain, heart, kidney, retina, or blood vessels. Typically, BP is 220/130 mm Hg or higher but may be much lower in women with preeclampsia who do not have preexisting hypertension such that cerebral autoregulation has not been reset. Hypertensive crises require immediate reduction of BP with intravenous medication and intra-arterial monitoring in an intensive care unit. In contrast, *hypertensive urgency* denotes severe uncontrolled hypertension without evidence of acute target-organ damage. In the absence of symptoms and acute target-organ damage, a patient with a BP of 220/130 mm Hg should be treated with a short-acting oral medication. *Severe hypertension*, defined as a BP of 180/110 mm Hg to 220/130 mm Hg without symptoms or acute target-organ damage, almost always occurs in patients with chronic hypertension who ran out of or stopped taking their BP medication. Long-acting oral medication can simply be restarted. Patients with either hypertensive urgency or severe hypertension require outpatient follow-up within 24 to 72 hours by either a primary care physician or hypertension specialist.

Management of Specific Hypertensive Crises

Adapted from the updated Dutch guidelines,¹¹⁹ **Table 44-12** summarizes treatment recommendations for hypertensive crises by affected organ system. **Table 44-13** summarizes the recommended parenteral drugs for treatment of hypertensive crises.

Hypertensive Crisis with Advanced Retinopathy

Patients with full-blown hypertensive crisis are critically ill with a BP of 220/130 mm Hg or higher and grade 3 or grade 4 hypertensive retinopathy (**Fig. 44-9**) accompanied by several of the following: headache, visual disturbances, nausea/vomiting, heart failure, neurologic sequelae (encephalopathy), electrocardiographically confirmed LVH, renal impairment, and microangiopathic hemolytic anemia. Black American patients are more likely to have hypertensive heart failure.¹²⁰ First-line drug options are intravenous labetalol (a combined alpha/beta blocker), nitroprusside, nicardipine (a dihydropyridine CCB), or urapidil (a new central sympatholytic that acts on central serotonergic pathways and also selectively blocks peripheral alpha₁-adrenergic receptors). In patients with impaired cerebral autoregulation (see below), labetalol causes a smaller adverse fall in cerebral blood flow than nitroprusside does but has a longer half-life, which leads to more adverse episodes of systemic hypotension.¹²¹ Intravenous nicardipine appears to produce a more predictable and consistent reduction in BP than labetalol does, but with a similar safety profile; however, physicians and hospital pharmacies are less familiar with nicardipine.¹²²

Hypertensive Crisis with Encephalopathy

Hypertensive encephalopathy is characterized by a reduced level of consciousness, delirium, agitation, stupor, seizures, or cortical blindness in the setting of acute severe high BP. Focal neurologic signs are rare and suggest ischemic or hemorrhagic stroke rather than encephalopathy. Hypertensive encephalopathy is a cause of reversible posterior leukoencephalopathy syndrome, which is often seen in the setting of cyclosporine- or tacrolimus-induced hypertension (particularly in heart transplant recipients) or that caused by bevacizumab or bortezomib. Brain computed tomography or magnetic resonance imaging showing areas of cerebral edema confirms the diagnosis of encephalopathy. The edema typically localizes in posterior brain regions perfused by the vertebral arteries, which have less sympathetic innervation and thus less dampening of BP oscillations than the carotid arteries do. The areas of brain edema will resolve with timely treatment of the hypertensive crisis.

TABLE 44-12 Intravenous Drugs for Treatment of Hypertensive Emergencies

DRUG	ONSET OF ACTION	HALF-LIFE	DOSE	CONTRAINDICATIONS AND SIDE EFFECTS
Labetalol	5-10 min	3-6 hr	0.25-0.5 mg/kg; 2-4 mg/min until goal BP is reached, thereafter 5-20 mg/hr	Second-degree or third-degree AV block; systolic heart failure, COPD (relative); bradycardia
Nicardipine	5-15 min	30-40 min	5-15 mg/hr as continuous infusion, starting dose of 5 mg/hr, increase q15-30 min with 2.5 mg until goal BP achieved, thereafter decrease to 3 mg/hr	Liver failure
Nitroprusside	Immediate	1-2 min	0.3-10 µg/kg/min, increase by 0.5 µg/kg/min q5 min until goal BP achieved	Liver/kidney failure (relative), cyanide toxicity
Nitroglycerin	1-5 min	3-5 min	5-200 µg/min, 5-µg/min increase q5 min	
Urapidil	3-5 min	4-6 hr	12.5-25 mg as bolus injections; 5-40 mg/hr as continuous infusion	
Esmolol	1-2 min	10-30 min	0.5-1.0 mg/kg as bolus; 50-300 µg/kg/min as continuous infusion	Second-degree or third-degree AV block, systolic heart failure, COPD (relative); bradycardia
Phentolamine	1-2 min	3-5 min	1-5 mg, repeat after 5-15 min until goal BP is reached; 0.5-1 mg/hr as continuous infusion	Tachyarrhythmia, angina pectoris

AV = atrioventricular; COPD = chronic obstructive pulmonary disease.

Modified from van den Born BJ, Beutler JJ, Gaillard CA, et al: Dutch guideline for the management of hypertensive crisis—2010 revision. *Neth J Med* 69:248, 2011.

TABLE 44-13 Recommended Treatment of Hypertensive Emergencies by End-Organ Involved

TYPE OF EMERGENCY	TIMELINE, TARGET BLOOD PRESSURE	FIRST-LINE THERAPY	ALTERNATIVE THERAPY
Hypertensive crisis with retinopathy, microangiopathy, or acute renal insufficiency	Several hours, MAP –20% to –25%	Labetalol	Nitroprusside Nicardipine Urapidil
Hypertensive encephalopathy	Immediate, MAP –20% to –25%	Labetalol	Nicardipine Nitroprusside
Acute aortic dissection	Immediate, SBP < 110 mm Hg	Nitroprusside + metoprolol	Labetalol
Acute pulmonary edema	Immediate, MAP 60 to 100 mm Hg	Nitroprusside with loop diuretic	Nitroglycerin Urapidil with loop diuretic
Acute coronary syndrome	Immediate, MAP 60 to 100 mm Hg	Nitroglycerin	Labetalol
Acute ischemic stroke and BP >220/120 mm Hg	1 hour, MAP –15%	Labetalol	Nicardipine Nitroprusside
Cerebral hemorrhage and SBP >180 mm Hg or MAP >130 mm Hg	1 hour, SBP < 180 mm Hg and MAP <130 mm Hg	Labetalol	Nicardipine Nitroprusside
Acute ischemic stroke with indication for thrombolytic therapy and BP >185/110 mm Hg	1 hour, MAP less than –15%	Labetalol	Nicardipine Nitroprusside
Cocaine/XTC intoxication	Several hours, SBP < 140 mm Hg	Phentolamine (after benzodiazepines)	Nitroprusside
Pheochromocytoma crisis	Immediate	Phentolamine	Nitroprusside Urapidil
Perioperative hypertension during or after CABG	Immediate	Nicardipine	Urapidil Nitroglycerin
During or after craniotomy	Immediate	Nicardipine	Labetalol
Severe preeclampsia/eclampsia	Immediate, BP < 160/105 mm Hg	Labetalol (plus MgSO ₄ and oral antihypertensives)	Ketanserin Nicardipine

CABG = coronary artery bypass graft; MAP = mean arterial pressure; MgSO₄ = magnesium sulfate; XTC = Ecstasy.

Modified from van den Born BJ, Beutler JJ, Gaillard CA, et al: Dutch guideline for the management of hypertensive crisis—2010 revision. *Neth J Med* 69:248, 2011.

FIGURE 44-9 Retinal photographs showing the stages of hypertensive retinopathy. **A**, Mild diffuse arteriolar narrowing. **B**, Arteriovenous nicking (arrow). **C**, Hemorrhages and exudates. **D**, Papilledema. (From Grosso A, Veglio F, Porta M, et al: Hypertensive retinopathy revisited: Some answers, more questions. *Br J Ophthalmol* 89:1646, 2005.)

Encephalopathy occurs when BP exceeds the upper limit of cerebral autoregulation, which normally maintains cerebral blood flow constant over a range of mean arterial pressure from 60 to 150 mm Hg. In patients without preexisting hypertension, such as those with preeclampsia, encephalopathy will develop when mean arterial pressure exceeds 150 mm Hg. In those with chronic hypertension, the autoregulatory curve shifts to the right to defend against a higher level of BP, but this adjustment makes patients vulnerable to cerebral underperfusion if BP is lowered too quickly into the normotensive range. Thus patients with hypertensive encephalopathy should receive intravenous antihypertensive therapy—preferably with labetalol—immediately to lower BP in a controlled manner that avoids cerebral hypoperfusion and thus irreversible brain damage. A good rule of thumb is to lower the initially elevated arterial pressure by 10% in the first hour and by an additional 15% during the next 12 hours to a BP of no less than 160/110 mm Hg. BP can be reduced further during the next 48 hours. Intravenous saline is often needed to prevent hypovolemic hypotension from pressure natriuresis and nausea/vomiting.

Acute Ischemic or Hemorrhagic Stroke

In acute ischemic stroke, BP should be lowered cautiously to avoid ischemic insult to potentially salvageable tissue (termed the *ischemic penumbra*), which would extend the infarct.¹²³ Acknowledging a limited evidence base, the 2013 guidelines from the AHA/American Stroke Association¹²⁴ recommend the following: (1) if the stroke cannot be treated with thrombolytic therapy, BP should be treated if it remains higher than 220/120 mm Hg and initially lowered by no more than 15%, and (2) if the stroke can be treated with thrombolytic therapy, BP needs to be lowered to less than 185/110 mm Hg. Recent results of INTERACT2 (Intensive BP Reduction in Acute Hemorrhage Trial 2) showed improved functional outcomes without more adverse events in patients with acute hemorrhagic stroke randomly assigned to intensive treatment to lower SBP to less than 140 mm Hg than to the conservative guideline-recommended goal of less than 180 mm Hg.¹²⁵ For either ischemic or hemorrhagic stroke, agents of choice to lower BP include urapidil, nicardipine, or labetalol; nitroprusside and hydralazine should be avoided.

Acute Coronary Syndrome (See also Chapters 52 and 53)

In hypertensive patients with acute coronary syndrome, BP should be lowered with intravenous nitroglycerin after the administration of a beta blocker such as intravenous metoprolol or esmolol to prevent reflex tachycardia. Experience is limited with the alternatives labetalol or urapidil. Nitroprusside can cause coronary steal and should be avoided. Hypotension must be avoided to prevent infarct extension.

Acute Heart Failure (See also Chapter 24)

Nitroprusside is the drug of choice to treat hypertensive crisis and acute heart failure. Concomitant loop diuretics both decrease acute pulmonary edema and further lower BP.

Adrenergic Crisis

Pheochromocytoma crisis should be treated acutely with phentolamine followed by administration of a beta blocker. Nitroprusside and urapidil are effective alternatives. Clonidine withdrawal can be aborted by reintroduction of this agent. Based on limited evidence, cocaine- or methamphetamine-induced acute hypertension should be treated with intravenous benzodiazepines followed by phentolamine.

PRACTICAL CLINICAL APPROACH TO THE EVALUATION AND MANAGEMENT OF AMBULATORY HYPERTENSIVE PATIENTS

The long-awaited report issued by individuals appointed to the JNC 8 committee has recommended treatment goals that strictly reflect

the current evidence base from RCTs.⁹ This new guideline also recommends different approaches to pharmacotherapy for hypertension in individuals younger and older than 60 years and in blacks and non-blacks. This report has already engendered considerable discussion. The most clinically urgent issue raised by commentators regards the strict reliance on RCT evidence with less weight given to observational data.¹²⁶ Because we lack clinical trials that rigorously address some key issues in important ethnic and age groups, some argue that observational data deserve more weight to provide information on gaps in the clinical trial evidence base. Others respond that observational data do not assess in a rigorous manner the net health effects of the antihypertensive treatments used to achieve the goals associated with better outcomes in observational data. We refer the reader to the editorials that accompany the 2014 guideline for a more ample discussion of these issues.¹²⁶⁻¹²⁸

Unlike the previous JNC 1 to JNC 7 reports, the final 2014 report of the panel members appointed to the JNC 8 committee is not sanctioned by the NHLBI or any professional organization and thus does not constitute an official U.S. hypertension guideline.⁹ The recommendations overlap in some ways but also differ in others from other recent guidelines from several professional hypertension and cardiology organizations in the United States, Canada, and Europe. The 2014 report does not address home and ambulatory BP monitoring, medication noncompliance, physician inertia, and other important issues in translating an imperfect evidence base into clinical practice. Although the targets for treatment of hypertension remain controversial, from a public health perspective, many individuals at risk from hypertension do not receive treatment at all or do not approach achieving even the less stringent BP goals put forth in the 2014 report. We therefore offer the following additional suggestions for practical office-based evaluation and management of hypertension.

Initial Evaluation (See Chapter 43)

- **Office BP.** Hypertension is diagnosed if the average of multiple office seated BP readings is 140/90 mm Hg or higher and the patient has electrocardiographically (or echocardiographically) confirmed LVH or other evidence of hypertension-induced target-organ damage.
- **Home or Ambulatory BP Monitoring.** In the absence of target-organ damage or very severe office BP (>180/110 mm Hg), home or ambulatory BP monitoring is important to accurately stage the hypertension, set treatment goals, and monitor therapy. Home or ambulatory monitoring should be considered to detect masked hypertension, which is an indication for BP medication, if office BP is in the prehypertensive range (120 to 139/80 to 89 mm Hg) in patients with diabetes or CKD, who have a high prevalence of masked hypertension, and in black patients, who have a high prevalence of nocturnal hypertension. Home or ambulatory BP monitoring is critically important in elderly patients because white coat hypertension, masked hypertension, and orthostatic/postprandial hypotension are so prevalent in this population; office readings alone risk undertreatment or overtreatment of BP. Hypertension is diagnosed if the average home BP or the daytime ambulatory BP is 135/85 mm Hg or higher or if the average 24-hour BP is 130/80 mm Hg or higher.
- **Global CV Risk Assessment.** Most hypertensive patients seen by cardiologists have additional CV risk factors that need to be addressed with lifestyle modification alone or in combination with drug therapy. Such concomitant conditions include hyperlipidemia requiring statin therapy, metabolic syndrome, frank diabetes, CKD, and cigarette smoking.
- **Secondary Hypertension.** Screening for secondary hypertension is indicated in patients with early-onset hypertension (<30 years) and in all patients with truly resistant hypertension, adrenal incidentaloma, or specific clues detected on the routine initial evaluation. Unprovoked hypokalemia should prompt evaluation for primary aldosteronism via spot plasma renin and serum aldosterone measurements; BP medications do not need to be withheld. If screening is positive, confirmation of the diagnosis requires salt suppression testing and then adrenal vein sampling in an experienced center

to determine whether the patient has a unilateral aldosterone-producing adenoma, which is an indication for laparoscopic adrenalectomy. An adrenal incidentaloma is an indication to screen for pheochromocytoma and Cushing syndrome, as well as primary aldosteronism. Normal spot plasma fractionated metanephrine levels exclude pheochromocytoma. Normal dexamethasone suppression test results and 24-hour urinary cortisol levels exclude Cushing syndrome. A young woman with hypertension should be screened for fibromuscular renal artery stenosis with a computed tomography or magnetic resonance angiography because balloon angioplasty can be curative. Because of poor outcomes with renal artery stenting in older patients with atherosclerotic renal artery stenosis, workup should be limited to those with suspected bilateral stenosis (often raised by ACEI-induced acute renal impairment) or a small unilateral kidney with either progressive renal failure or drug-resistant hypertension.

Management

- **Lifestyle Modification.** The DASH diet and other lifestyle modifications are indicated for all patients with hypertension or prehypertension as detailed in the 2013 AHA/ACC guideline on lifestyle management to reduce CV risk.¹⁷ Because recidivism is common, patients need continual encouragement from their physicians and support from family and peers.
- **BP Treatment Goals.** Because of gaps in the evidence base, recommended BP treatment goals are the subject of much debate. For general hypertensive patients, most current guidelines recommend initiating or intensifying medication until the mean office BP is lower than 140/90 mm Hg and the mean home BP is lower than 135/85 mm Hg. In other words, office BP readings mostly in the 130s/80s and home BP readings mostly in the high 120s/70s to low 130s/80s without medication side effects indicate excellent hypertension management. In hypertensive older adults, we recommend modifying these general treatment targets based on overall health status and biologic age rather than chronologic age. A seated home BP of 155 mm Hg may be an appropriate treatment target for a frail 70-year-old patient with marked orthostatic and postprandial hypotension (as in Fig. 44-7), whereas a home seated BP of 130 mm Hg may be an appropriate treatment target for a vigorous healthy 85-year-old patient whose chief concern is to avoid a disabling stroke. Symptomatic orthostatic hypotension must be avoided, particularly when treating older adults and patients with longstanding diabetes in whom autonomic neuropathy has developed. For most patients with uncomplicated diabetes, we recommend the same office and home BP goals as for general hypertensive individuals. For patients with nonproteinuric CKD (regardless of whether diabetic), most of the new guidelines recommend a goal office seated BP of lower than 140/90 mm Hg and lower than 130/80 mm Hg for those with proteinuric CKD. We recommend ambulatory BP monitoring at least once for any patient with stage 3 or higher CKD because masked and nocturnal hypertension will be present in most and lead to undertreatment of hypertension and because overtreatment of hypertension can precipitate acute renal decompensation; as a rule of thumb, home BP should be lower than 135/85 mm Hg and nighttime BP lower than 120/70 mm Hg, but these goals will require relaxation if renal function deteriorates in patients with advanced CKD because of the loss of renal autoregulation. RCTs are urgently needed to determine the optimal home and ambulatory (nocturnal) BP treatment targets for black patients and other high-risk groups.
- **First-Line Drugs.** The three first-line drug classes for treating hypertension are (1) a CCB, (2) an ACEI or ARB, and (3) a thiazide. We recommend amlodipine as the preferred CCB for most patients because it is long acting (once-daily dosing), is the best studied of the CCBs and performed well in multiple RCTs, and is now available in generic form. The choice of an ACEI or ARB involves consideration of cost and tolerability. We recommend a long-acting ACEI or ARB for once-daily dosing. For diuretic therapy, the evidence overwhelmingly favors chlorthalidone (12.5 to 25 mg/day) over HCTZ.⁵⁹

Lower doses of chlorthalidone (e.g., 6.25 to 12.5 mg) may minimize side effects, but doses below 12.5 mg have undergone limited evaluation in outcome trials.

- **Low-Dose Combination Therapy.** Low-dose combination drug therapy using any two or three of the first-line antihypertensive agents should be considered for all patients with hypertension. High doses should be avoided whenever possible to avoid dose-dependent side effects and toxicity. For most hypertensive patients, a CCB/ACEI (or ARB) combination is typically well tolerated, very effective, and supported by RCTs, but evidence also supports ACEI/diuretic or CCB/diuretic combinations. Because BP reduction rather than drug class accounts for most CV protection with antihypertensive drugs, the choice of drugs often comes down to what drugs an individual patient can tolerate well and afford. Long-term adherence is best for ARBs, intermediate for ACEIs and CCBs, and least for diuretics and beta blockers. Thus combination therapy with a CCB plus an ARB (or an ACEI if cost is an issue) is an excellent option to initiate therapy regardless of age or race. Outcomes of monotherapy-based trials tend to underestimate the effectiveness of RAS blockers when used as combination therapy in black patients and elderly patients with low-renin hypertension. Fixed-dose single-pill combinations that decrease pill burden include virtually every ACEI or ARB plus either amlodipine or HCTZ; recently, triple-therapy single-pill combinations have become available but with HCTZ rather than chlorthalidone.
- **Resistant Hypertension.** Many cases of difficult hypertension are pseudoresistant. If white coat hypertension and medication compliance have been excluded, NSAIDs have been eliminated, and the goal BP still cannot be achieved with standard triple therapy (amlodipine *plus* a long-acting ACEI or ARB *plus* chlorthalidone), the best add-on drugs are mineralocorticoid receptor antagonists (spironolactone, eplerenone) and vasodilating beta blockers (carvedilol, nebivolol). Low-dose spironolactone (12.5 to 25 mg/day) may take 8 weeks to achieve peak BP reduction, which can be impressive. Eplerenone avoids the sexual side effects of spironolactone but is more expensive and higher doses (50 to 100 mg) may be required. Clonidine should be avoided whenever possible and never be prescribed for patients to self-medicate on an as-needed basis because this practice will create labile rebound hypertension.

Table 44-14 furnishes tips on optimal BP management. Undertreatment of hypertension and underuse of combination drug therapy—even for resistant hypertension—is common in outpatient office-based practice.¹²⁹⁻¹³¹ Impressive new data from Kaiser-Permanente show that a large managed care organization can improve hypertension control rates in their population from 45% to an astounding 80% by (1) continually reviewing their registry data to identify patients with elevated BP and contacting the patients proactively, (2) using a simple system-wide medication intensification protocol with fixed-dose/once-daily

TABLE 44-14 Strategies to Optimize Management of Hypertension

combination pills, and (3) increasing access with walk-in BP checks performed by medical assistants who are part of a pharmacist-based hypertension management team.¹³² Pharmacists can work with patients to develop shared goals and reconcile medications, and in most states they can implement a preset medication intensification protocol under collaborative practice agreement with physician oversight. Pharmacist-based team interventions for the management of hypertension have proved effective in more than 40 RCTs¹³³ and allow the physician time to focus on health care team leadership, diagnostic evaluations, and other complex issues.¹³⁴

With all these measures, hypertension control rates of up to 80% can be achieved in office-based practice. Patients with drug-resistant hypertension should be referred to a hypertension specialist (www.ash-us.org/HTN-Specialist.aspx).

FUTURE PERSPECTIVES

Catheter-based RDN is the most exciting development in hypertension. With the unexpectedly negative primary outcome of the Sym- plicity HTN-3 trial, much more work is needed to determine its ultimate impact on CV therapeutics. More than 40 companies are developing new catheters and alternative modes of RDN, which may be more effective than radiofrequency denervation. Substantial technical improvements have been made in the carotid baroreceptor pacemaker, and a new pivotal trial is under way. Carotid body denervation is in early stages of investigation.

ACKNOWLEDGMENT

The authors wish to thank Dr. Norman M. Kaplan, who contributed to previous editions of this chapter.

GUIDELINES

Treatment of Hypertension

Ronald G. Victor and Peter Libby

New hypertension practice guidelines from at least 10 expert committees in the United States, Canada, and Europe have been published since the last edition of this textbook.¹⁻¹⁰ The recommendations have become progressively more evidence based. The 2014 report of the Eighth Joint National Committee (referred to as JNC 8 for convenience) members is the most strictly evidence-based set of hypertension guidelines produced to date.¹¹ Treatment recommendations are based on strict interpretation of data only from randomized controlled trials (RCTs) of hypertension; major RCTs of antihypertensive agents were excluded from consideration if the study population included patients with high risk for atherosclerotic cardiovascular disease (ASCVD), with or without hypertension. Unlike past JNC reports, JNC 8 is not a comprehensive set of practice guidelines. Before JNC 8 was finalized in 2013, the National Heart, Lung and Blood Institute (NHLBI) decided that it would no longer sanction professional practice guidelines. Although the final report underwent extensive peer review before being published by the *Journal of the American Medical Association*,¹² JNC 8 differs from preceding JNC reports in that it was neither endorsed by NHLBI nor reviewed or endorsed by any professional medical society and thus does not constitute the official U.S. hypertension guidelines. As a result, other practice guidelines appeared in 2014 from the American Society of Hypertension (ASH)/International Society of Hypertension (ISH)² and from the American College of Cardiology Foundation/American Heart Association/Centers for Disease Control and Prevention (ACCF/AHA/CDC).³

DIAGNOSIS OF HYPERTENSION

An initially elevated office blood pressure (BP)—higher than 140 mm Hg systolic or 90 mm Hg diastolic—must always be confirmed either by home or ambulatory BP monitoring, as emphasized by both the new European guidelines⁴ and updated U.K. guidelines,⁸ or must be remeasured at least three times over a period of at least 4 weeks to ensure that hypertension is present (Table 44-G1). Only if the office BP level is very high ($\geq 180/110$ mm Hg) or if symptomatic target-organ damage is present should therapy begin before the diagnosis is carefully established.

TABLE 44-G1 Definition of Hypertension by Office and Out-of-Office Blood Pressure Levels

CATEGORY	SYSTOLIC BLOOD PRESSURE (mm Hg)	DIASTOLIC BLOOD PRESSURE (mm Hg)
Office BP	≥ 140	and/or ≥ 90
Home BP	≥ 135	and/or ≥ 85
Ambulatory BP		
Daytime (or awake)	≥ 135	and/or ≥ 85
Nighttime (or sleep)	≥ 120	and/or ≥ 70
24 hour	≥ 130	and/or ≥ 80

Modified from Mancia G, Fagard R, Narkiewicz K, et al: 2013 ESH/ESC guidelines for the management of arterial hypertension: The Task Force for the Management of Arterial Hypertension of the European Society of Hypertension (ESH) and of the European Society of Cardiology (ESC). *J Hypertens* 31:1281, 2013.

MANAGEMENT OF HYPERTENSION

Lifestyle Modification

All patients with hypertension or prehypertension (BP of 120 to 139/80 to 89 mm Hg) should receive counseling on lifestyle modification according to the 2013 ACCF/AHA guidelines on lifestyle management to reduce cardiovascular (CV) risk.¹³

Drug Therapy

Table 44-G2 summarizes the major differences between the 2003 JNC 7 recommendations¹⁴ and common features shared by the new recommendations of JNC 8,¹ the 2013 European Society of Hypertension/European Society of Cardiology (ESH/ESC) guidelines,⁴ the 2011 U.K. National Center for Clinical Excellence (NICE; now called National Center for Care Excellence) guidelines,⁸ and the 2011 ACCF/AHA guidelines on treatment of hypertension in the elderly.⁹ JNC 7 recommended 140/90 mm Hg or higher as the office BP threshold for initiation of antihypertensive drug therapy in most patients, regardless of age, and a lower than usual threshold of 130/80 mm Hg or higher for patients with diabetes mellitus or chronic kidney disease (CKD). The new guidelines have relaxed the BP threshold for initiation of drug therapy to 150/90 mm Hg or higher for elderly patients and have eliminated the 130/80 mm Hg or higher threshold for patients with diabetes or CKD—who now have the same 140/90 mm Hg or higher treatment threshold recommended for most other hypertensive patients.

JNC 7 recommended a thiazide diuretic as the best choice to initiate drug therapy for most cases of hypertension. In contrast, the new guidelines recommend initiating therapy with one or more of three first-line drug classes: a calcium channel blocker (CCB), an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB), and/or a thiazide. Chlorthalidone has replaced hydrochlorothiazide (HCTZ) as the preferred thiazide because of its greater potency, longer duration of action, and much larger evidence base.¹⁵ Although JNC 7 reserved combination drug therapy for mainly stage 2 hypertension (BP $\geq 160/110$ mm Hg), the new guidelines recognize that low-dose combination therapy is an excellent way to initiate drug therapy even for those with mild hypertension. An ACEI (or ARB) plus CCB combination is at least as effective—and possibly more effective—than an ACEI (or ARB) plus thiazide combination. A CCB plus thiazide is also an effective

TABLE 44-G2 Comparison of 2003 JNC 7 Guidelines with New Recommendations Common to the Guidelines by the 2014 JNC 8 Committee, 2013 ESH/ESC, 2011 UK-NICE, and 2011 ACCF/AHA

	2003 JNC 7 REPORT	2011-2014 GUIDELINES
Blood pressure threshold for initiation of drug therapy	$\geq 140/90$ mm Hg for most patients $\geq 130/80$ mm Hg for patients with diabetes or CKD	$\geq 150/90$ mm Hg for elderly patients* $\geq 140/90$ mm Hg for nonelderly patients and patients with diabetes or CKD
First-line therapy	Thiazide diuretic for most patients	Three first-line drug classes: CCB, ACEI or ARB, thiazide
Preferred thiazide	HCTZ	Chlorthalidone
Combination drug therapy	Mainly for stage 2 hypertension ACEI + thiazide	A good option for stage 1 hypertension ACEI + CCB \geq ACEI + thiazide

*Only JNC 8 defines “elderly” as 60 years or older; the other guidelines define “elderly” as 80 years or older or based more on frailty than on a specific chronologic age.
Modified from James PA, Oparil S, Carter BL, et al: 2014 Evidence-based guideline for the management of high BP in adults: Report from the panel members appointed to the Eighth Joint National Committee (JNC 8). *JAMA* 311:507, 2014.

combination, but ACEI plus ARB combinations and ACEI (or ARB) plus aliskiren combinations should be avoided because they promote hypotension and worsen renal function.¹

Table 44-G3 compares the 10 sets of hypertension guidelines published between 2010 and 2014. With gaps in the evidence base, expert panels and individual panelists disagree on some aspects but agree on others about when to start (or intensify) therapy and about which drugs are best for which patients. Several points should be emphasized.

When to Start or Intensify Therapy?

- Most of the new guidelines have raised the seated office BP threshold for initiation/intensification of drug therapy in hypertensive elderly patients to 150/90 mm Hg or higher, except for an even more conservative recommendation of 160/90 mm Hg or higher by the 2013 ESH/ESC guidelines.⁴
- Only JNC 8 defines “elderly” as 60 years or older. The other guidelines define elderly as 80 years or older. Several JNC 8 panel members did not support this definition and wrote a minority view position paper¹⁶ citing the following evidence supporting a BP treatment threshold of 140 mm Hg systolic for patients 60 to 79 years of age:

- Increasing the BP treatment threshold to 150 mm Hg systolic and the treatment target to 140 to 149 mm Hg (rather than 10 mm Hg lower) will probably reduce the intensity of antihypertensive therapy in the large population at highest risk for hypertensive complications—including black adults (as incorporated into the 2013 ACC/AHA pooled cohort ASCVD risk calculator).¹⁷
- Evidence supporting the new higher (SBP of 150 mm Hg) threshold was based on insufficient evidence.
- The higher SBP goal in patients 60 years or older runs the considerable risk of increasing the population-level BP and reversing the progressive decline in CV disease, especially stroke.
- Most guidelines have raised the office BP treatment threshold in patients with diabetes mellitus to 140/90 mm Hg or higher—except for the 2013 American Diabetes Association (ADA) guidelines,⁶ which recommend 140/80 mm Hg or higher, and the 2013 Canadian guidelines,⁵ which still recommend 130/80 mm Hg or higher.
- Most guidelines have raised the treatment threshold in CKD to 140/90 mm Hg or higher, except for the 2012 Kidney Disease Improving Global Outcomes (KDIGO) guidelines,⁷ which recommend 130/80 mm Hg or higher for proteinuric CKD.
- All but the three most recent sets of guidelines from the United States use global ASCVD risk in deciding when to initiate therapy.

TABLE 44-G3 Comparison of Recent Guidelines for Adults with Hypertension

GUIDELINE	POPULATION	THRESHOLD OFFICE BLOOD PRESSURE LEVEL (mm Hg) FOR INITIATION OR INTENSIFICATION OF THERAPY	INITIAL DRUG THERAPY OPTIONS
2014 JNC 8 Committee ¹	General ≥ 60 yr General < 60 yr Diabetes CKD	≥150/90 ≥140/90 ≥140/90 ≥140/90	Nonblack: thiazide,* ACEI or ARB, CCB Black: thiazide, CCB Thiazide, ACEI or ARB, CCB ACEI or ARB
2014 ASH/ISH ²	General ≥ 80 yr General < 80 yr Diabetes CKD	≥150/90 ≥140/90 ≥140/90 ≥140/90	Nonblack/stage 1: thiazide, ACEI or ARB, CCB Black/stage 1: thiazide, CCB Stage 2: CCB or thiazide + ACEI or ARB ACEI or ARB ACEI or ARB
2013 AHA/ACC/CDC ³	General	≥140/90	Stage 1: thiazide for most or ACEI or ARB, CCB Stage 2: thiazide + ACEI or ARB or thiazide + CCB or ACEI or ARB + CCB
2013 ESH/ESC ⁴	General ≥ 80 yr General 60-79 yr General ≤ 60 yr Diabetes CKD, no proteinuria CKD + proteinuria	≥160/90 ≥150/90 or ≥140/90 ≥140/90 ≥140/85 ≥140/90 ≥130/90	Beta blocker, thiazide, CCB, ACEI or ARB ACEI or ARB ACEI or ARB ACEI or ARB
2013 CHEP ⁵	General ≥ 80 yr General < 80 yr Diabetes CKD	≥150/90 ≥140/90 ≥130/80 ≥140/90	Thiazide, beta blocker (<60 yr), ACEI or ARB (nonblack) ACEI or ARB (+ additional CVD risk); ACEI or ARB, thiazide, CCB (– additional CVD risk) ACEI or ARB
2013 ADA ⁶	Diabetes	≥140/80	ACEI or ARB
2012 KDIGO ⁷	CKD, no proteinuria CKD + proteinuria	≥140/90 ≥130/80	ACEI or ARB
2011 UK NICE ⁸	General ≥ 80 yr General < 80 yr	≥150/90 ≥140/90	≥55 yr or black: CCB, thiazide <55 yr: ACEI or ARB
2011 ACCF/AHA: elderly hypertensive patients ⁹	General ≥ 80 yr General < 80 yr	≥150/90 ≥140/90	ACEI or ARB, CCB, thiazide
2010 ISHIB ¹⁰	Black Black + target-organ disease or CVD risk	≥135/85 ≥130/80	Thiazide, CCB

*Evidence from randomized controlled trials supports the use of chlorthalidone, a thiazide-like diuretic, rather than hydrochlorothiazide.

ACC = American College of Cardiology; ADA = American Diabetes Association; AHA = American Heart Association; ASH = American Society of Hypertension; CDC = Centers for Disease Control and Prevention; CHEP = Canadian Hypertension Education Program; CVD = cardiovascular disease; ISH = International Society of Hypertension; KDIGO = Kidney Disease: Improving Global Outcome; UK NICE = U.K. National Institute for Health and Clinical Excellence.

Modified from James PA, Oparil S, Carter BL, et al: 2014 Evidence-based guideline for the management of high BP in adults: Report from the panel members appointed to the Eighth Joint National Committee (JNC 8). *JAMA* 311:507, 2014.

The European guidelines continue to be the most conservative and reserve drug therapy for stage 1 hypertension only for those with clinical CV disease, target-organ damage, diabetes, CKD, or an estimated 10-year CV disease risk of 20% or higher.⁴

- The 2010 International Society on Hypertension in Blacks (ISHIB) guidelines¹⁰ may be the least evidence based,¹⁸ but they also are the most risk based and recommend initiation of drug therapy with an office BP of 135/85 mm Hg or higher in black patients with uncomplicated hypertension (who are at higher risk than other groups for the development of complications) and for a BP of 130/80 mm Hg or higher in the presence of target-organ disease, comorbidity, or an estimated 10-year risk for CV disease of 10% or higher.

With all these guidelines, the goal of therapy is to achieve average systolic and diastolic BP levels just below the thresholds for initiating or intensifying therapy.

Which Drugs for Which Patients?

- There is general consensus that at the end of the day, the vast majority of hypertensive patients—regardless of age, race/ethnicity, and absence or presence of target-organ damage or comorbid conditions—will require triple combination drug therapy with a CCB, an ACEI or ARB, and a diuretic. The only issue is which drug or drugs to prescribe first.
- Most guidelines, including those of the ISHIB, prefer both a thiazide and a CCB over an ACEI or ARB to initiate therapy in black patients.
- There is overwhelming consensus that an ACEI or ARB is first-line antihypertensive therapy for patients with diabetes.
- There is overwhelming consensus that an ACEI or ARB is first-line antihypertensive therapy for patients with CKD.

Percutaneous Intervention

The 2013 ESC guidelines on catheter-based renal denervation¹⁹ will need to be reevaluated in light of a 2014 press release stating that the Symplicity HTN-3 trial failed to meet its primary efficacy endpoint.²⁰

Lipids constitute approximately 70% (by mass) of the dry weight of plasma. Amino acids (proteins), nucleic acids, and carbohydrate make up the remainder. Approximately half of circulating lipids are sterols, with the other major components being glycerophospholipids (phospholipids) and glycerolipids (triglycerides), which circulate in lipoproteins.¹ Thus vascular endothelial cells are continuously exposed to circulating lipoproteins, and the interaction between lipoproteins and cells of the arterial wall have major importance in the pathogenesis of human atherosclerosis (see also Chapter 41).

Accumulating data affirm the basic tenets of the “lipid hypothesis.” Observational data show a strong and consistent association across populations between elevated plasma (or serum) levels of cholesterol and low-density lipoprotein cholesterol (LDL-C) and cardiovascular disease, especially coronary artery disease (CAD). Chapter 42 presents the epidemiologic observational data on plasma lipids and lipoprotein lipids being a key component of cardiovascular risk factors. Experimental animal data show that the development of atherosclerosis requires cholesterol. Mendelian randomization analyses provide strong support of causality for genes related to LDL-C levels. Reduction of LDL-C levels reduces the risk for CAD, and the effect size is associated with the magnitude of the reduction in LDL-C.² Thus low-density lipoprotein (LDL) meets the modified Koch postulates as a causal risk factor for atherosclerotic cardiovascular disease (CVD).

Chapter 41 discusses the biologic basis and pathophysiology of atherosclerosis. This chapter deals with the fundamentals of lipid metabolism, therapeutic approaches to the treatment of lipid disorders, and the evidence base regarding their clinical use.

The terms *dyslipidemia* and *dyslipoproteinemia* reflect disorders of the lipid and lipoprotein transport pathways associated with arterial disease more appropriately than does the term *hyperlipidemia*, which has long been used in clinical practice. *Dyslipidemia* encompasses disorders often encountered in clinical practice, such as a low high-density lipoprotein cholesterol (HDL-C) level and elevated triglyceride level but an average total plasma cholesterol level. *Dyslipidemia* also includes elevated lipoprotein(a) (Lp[a]) and uncommon genetic or acquired disorders of lipoprotein metabolism. Certain rare lipoprotein disorders can cause overt clinical manifestations, but most common dyslipoproteinemias themselves seldom cause symptoms or produce clinical signs that are evident on physical examination. Rather, they require laboratory tests for detection. Proper recognition and management of dyslipoproteinemias can reduce cardiovascular and total mortality rates. The fundamentals of lipidology presented

here have importance for the daily practice of cardiovascular medicine.

LIPOPROTEIN TRANSPORT SYSTEM

Biochemistry of Lipids

Lipids are insoluble in water and soluble in organic solvents. Biologic lipids usually refer to a broad grouping of naturally occurring molecules that include fatty acids, waxes, eicosanoids, monoglycerides, diglycerides, triglycerides, phospholipids, sphingolipids, sterols, terpenes, prenols, and fat-soluble vitamins (A, D, E, and K), in contrast to the other major groupings of biologic molecules, namely, nucleic acids, proteins, amino acids, and carbohydrates. The major biologic functions of lipids include critical contributions to biologic membranes, energy storage, and the backbones or modifiers of many signaling molecules. Certain lipids, especially fatty acid, readily undergo oxidation and can generate substances highly toxic to cells. Fatty acids can be degraded in the mitochondrion by beta-oxidation, whereas the sterol nucleus resists enzymatic degradation. Cholesterol must therefore be modified into bile acids or hormones or be shed with the skin to be eliminated.

The lipid transport system has evolved in animals over eons of evolution to carry hydrophobic molecules (fat) from sites of origin (the intestinal system) to sites of utilization (muscles, rapidly dividing tissues, and hormone-producing tissues) through the aqueous (water) environment of plasma. The proteins that mediate this process, termed *apolipoproteins*, show conservation throughout evolution in organisms with a circulatory system. Most apolipoproteins are derived from an ancestral gene and contain both hydrophilic and hydrophobic domains. This amphipathic structure enables these proteins to bridge the interface between the aqueous environment of plasma and the phospholipid constituents of lipoprotein. The major types of lipids that circulate in plasma include cholesterol and cholesteryl esters, glycerophospholipids, sphingolipids, and glycerolipids (triglycerides) (Fig. 45-1). The LIPID MAPS (Lipid Metabolites and Pathways Strategy) consortium has provided standardized nomenclature for lipids.³

Cholesterol is an essential component of mammalian cell membranes and the membranes of subcellular organelles (endoplasmic reticulum, Golgi, mitochondria, lysosomes, nucleus, endosomes, peroxisomes) and furnishes the substrate for steroid hormones and bile

molecular cellular physiology and targets for drug development (Table 45-3). Discovery of the LDL receptor (LDL-R) represented a landmark in understanding cholesterol metabolism and receptor-mediated endocytosis.⁴ LDL-R regulates the entry of cholesterol into cells, and tight control mechanisms alter its expression on the cell surface, depending on need. LDL-R belongs to a superfamily of membrane receptors that includes LDL-R, VLDL-R, LDL-R-mediated peptide type 1 (LRP1; apo E receptor), LRP1B, LRP4 (MGEF7), LRP5 and LRP6 (involved in the process of bone formation), LRP8 (apo E receptor-2), and LRP9.⁵ LRP1, which mediates the uptake of chylomicron remnants and VLDL, preferentially recognizes apo E. LRP1 also interacts with hepatic lipase. The interaction between hepatocytes and the various lipoproteins containing apo E is complex and involves cell surface proteoglycans that provide scaffolding for lipolytic enzymes (lipoprotein lipase [LPL] and hepatic lipase) involved in recognition of remnant lipoproteins. Macrophages express receptors

that bind modified (especially oxidized) lipoproteins. These scavenger lipoprotein receptors mediate the uptake of oxidatively modified LDL into macrophages. In contrast to the exquisitely regulated LDL-R, high cellular cholesterol content does not suppress scavenger receptors, thereby enabling intimal macrophages to accumulate abundant cholesterol, become foam cells, and form fatty streaks. Sterol accumulation in the endoplasmic reticulum may lead to cell apoptosis via the unfolded protein response.⁶ Endothelial cells can also take up modified lipoproteins through a specific receptor, such as the oxidized LDL-R LOX-1.

At least three physiologically relevant receptors bind HDL particles: the scavenger receptor class B (SR-B1) and the adenosine triphosphate (ATP)-binding cassette transporters A1 (ABCA1) and G1 (ABCG1). SR-B1 is a receptor for HDL (also for LDL and VLDL, but with less affinity). SR-B1 mediates the selective uptake of HDL cholesteryl esters in steroidogenic tissues, hepatocytes, and

ACAT = acetyl-CoA acyltransferase.

endothelium. ABCA1 mediates cellular phospholipid (and possibly cholesterol) efflux and is necessary and essential for HDL biogenesis. The ABCG1 transporter transfers cellular cholesterol to spherical HDL particles.

Lipoprotein Metabolism and Transport

The lipoprotein transport system has two major roles: efficient transport of triglycerides from the intestine and liver to sites of utilization (fat tissue or muscle), and transport of cholesterol to peripheral tissues for membrane synthesis and steroid hormone production or to the liver for bile acid synthesis (**Fig. 45-4**).

Intestinal Pathway (Chylomicrons to Chylomicron Remnants)

Life requires fats. The human body derives essential fatty acids (linoleic acid, from which arachidonic acid is derived, and linolenic acid, which leads to the formation of eicosapentaenoic acid) that it cannot make from the diet. Fat typically furnishes 20% to 40% of daily calories. Triglycerides account for the major portion of ingested fats. For an individual consuming 2000 kcal/day, with 30% in the form of fat, this represents approximately 66 g of triglycerides and 250 mg (0.250 g) of cholesterol per day. The intestine has very efficient fat absorption mechanisms, probably evolved to maximize provision of the organism with nutrients under circumstances of limited or irregular availability of food.

On ingestion, lingual and pancreatic lipases hydrolyze triglycerides into FFAs and monoglycerides or diglycerides. Emulsification by bile salts leads to the formation of intestinal micelles. Micelles resemble lipoproteins in that they consist of phospholipids, free cholesterol, bile acids, diglycerides and monoglycerides, FFAs, and glycerol. The mechanism of micelle uptake by intestinal brush border cells still engenders debate. The Niemann-Pick C1-like 1 (NPC1L1) protein is

part of an intestinal cholesterol transporter complex and the target for the selective cholesterol absorption inhibitor ezetimibe (see later).⁷ After uptake into intestinal cells, fatty acids undergo re-esterification to form triglycerides and packaging into chylomicrons inside the intestinal cell and enter the portal circulation (**Fig. 45-4**, path ①). Chylomicrons contain apo B48, the amino-terminal component of apo B100. In the intestine, the apo B gene is modified during transcription into mRNA by substitution of a uracil for a cytosine via an apo B48-editing enzyme complex (ApoBec). This mechanism involves a cytosine deaminase and leads to a termination codon at residue 2153 and a truncated form of apo B. Only intestinal cells express ApoBec. Apo B48 does not bind to LDL-R. Intestinal cells absorb plant sterols (sitosterol, campesterol), sort these compounds into a separate cellular compartment, and resecret them into the intestinal lumen via the ABCG5/8 heterodimeric transporter. Mutations of the ABCG5/8 genes cause the rare disorder sitosterolemia.

Chylomicrons rapidly enter the plasma compartment after meals. In capillaries of adipose tissue or muscle cells in the peripheral circulation, chylomicrons encounter LPL, an enzyme attached to heparan sulfate proteoglycans, and present on the luminal surface of endothelial cells (**Fig. 45-4**, path ②). LPL activity is modulated by apo C-II and apo A-V (activators) and by apo C-III (an inhibitor). LPL has broad specificity for triglycerides; it cleaves all fatty acyl residues attached to glycerol, and in the process generates three molecules of FFA for each molecule of glycerol. Muscle cells rapidly take up fatty acids. Fatty acids provide the energy substrate for muscle contraction by the generation of ATP during beta-oxidation of fatty acyl residues in mitochondria. Adipose cells can store triglycerides made from fatty acids for energy utilization, a process that requires insulin. Conversely, hormone-sensitive lipase is a triglyceride lipase that is activated by cyclic adenosine monophosphate (cAMP) in response to stress and releases fatty acids from adipose tissues. Fatty acids can also bind to fatty acid-binding proteins and albumin and travel to the

TABLE 45-3 Lipoprotein Processing Enzymes, Receptors, Modulating Proteins

ABBREVIATION	NAME	ROLE	CHROMOSOME	HUMAN DISEASE

VLDL-R	Very low-density lipoprotein receptor	VLDL uptake	9q24	

liver, where they are repackaged in VLDL. Peripheral resistance to insulin can thus increase the delivery of FFAs to the liver with a consequent increase in VLDL secretion and increased apo B particles in plasma. As discussed later, this is one of the consequences of metabolic syndrome and type 2 diabetes. The remnant particles, derived from chylomicrons following LPL action, contain apo E and enter the liver for degradation and reutilization of their core constituents (Fig. 45-4, path ③).

Hepatic Pathway (Very Low-Density Lipoprotein to Intermediate-Density Lipoprotein)

Food is not always available, and dietary fat content varies. The body must ensure that triglyceride is readily available to meet energy demands. Hepatic secretion of VLDL particles serves this function (Fig. 45-4, path ④). VLDLs are TRLs smaller than chylomicrons (see Table 45-1 and Fig. 45-3). They contain apo B100 as their main lipoprotein. As opposed to apo B48, apo B100 contains a domain recognized by LDL-R (the apo B/E receptor). VLDL particles follow the same catabolic pathway through LPL as chylomicrons do (see Fig. 45-4, path ②). During hydrolysis of TRLs by LPL, an exchange of proteins and lipids takes place: VLDL particles (and chylomicrons) acquire apo C's and apo E, in part from HDL particles. VLDLs also exchange triglycerides for cholesteryl esters from HDL (mediated by cholesteryl ester transfer protein [CETP]) (Fig. 45-4, path ⑤). Such bidirectional transfer of constituents between lipoproteins serves several purposes: acquisition of specific apolipoproteins by lipoproteins that will dictate their metabolic fate, transfer of phospholipids onto nascent HDL particles mediated by phospholipid transfer protein (PLTP) (during loss of the core triglycerides, the phospholipid

envelope becomes redundant and sheds apo A-I to form new HDL particles), and transfer of cholesterol from HDL to VLDL remnants so that it can be metabolized in the liver. This exchange constitutes a major part of the “reverse cholesterol transport pathway.”

After hydrolysis of triglycerides partly depletes VLDL of triglycerides, VLDL particles have relatively more cholesterol, shed several apolipoproteins (especially the C apolipoproteins), and acquire apo E. The VLDL remnant lipoprotein, called intermediate-density lipoprotein (IDL), is taken up by the liver via its apo E moiety (see Fig. 45-4, path ③) or is further delipidated by hepatic lipase to form an LDL particle (Fig. 45-4, path ⑥). At least four receptors take up TRLs, TRL remnants, and apo B-containing lipoproteins: VLDL-R, the remnant receptor (apo ER2), LDL-R (also called the apo B/E receptor), and LRP1. Most hepatic receptors share the ability to recognize apo E, an engagement that mediates the uptake of several classes of lipoproteins, including VLDL and IDL.⁵ The interaction between apo E and its ligand is complex and involves the “docking” of TRLs on heparan sulfate proteoglycans before presentation of the ligand to its receptor.

Low-Density Lipoproteins

LDL particles contain predominantly cholesteryl esters packaged with the protein moiety apo B100. Normally, triglycerides constitute only 4% to 8% of the LDL mass (see Table 45-1). In the presence of elevated plasma triglyceride levels, LDL particles can become enriched in triglycerides and depleted in core cholesteryl esters. Variation in LDL particle size results from changes in core constituents, with an increase in triglycerides and a relative decrease in cholesteryl esters leading to smaller, denser LDL particles.

FIGURE 45-4 Schematic diagram of the lipid transport system. Numbers in circles refer to explanations in text. CETP = cholesteryl ester transfer protein; CM = chylomicron; EL = endothelial lipase; HL = hepatic lipase; IDL = intermediate-density lipoprotein; PLTP = phospholipid transfer protein.

Humans are unusual among mammals in that they use LDL as a major cholesterol transporter. Nonhuman primates fed a cholesterol-enriched diet also carry cholesterol in LDL. In other mammals, such as rodents or rabbits, VLDL carries triglycerides, and HDL particles transport most of the cholesterol. Cells can either make cholesterol from acyl coenzyme A (CoA) through enzymatic reactions requiring at least 33 steps, or obtain it as cholesteryl esters from HDL and LDL particles. Cells internalize LDL via LDL-R (Fig. 45-5A). LDL particles contain one molecule of apo B. Although several domains of apo B are highly lipophilic and associated with phospholipids, a region surrounding residue 3500 binds with high affinity to LDL-R. LDL-R is localized in a region of the plasma membrane rich in the protein clathrin (Fig. 45-5A; also Fig. 45-4, path 7). Once bound to the receptor, clathrin polymerizes and forms an endosome that contains LDL bound to its receptor, a portion of the plasma membrane, and clathrin. This internalized particle then fuses with lysosomes whose hydrolytic enzymes (cholesteryl ester hydrolase, cathepsins) release free cholesterol and degrade apo B. LDL-R will detach itself from its ligand and recycle to the plasma membrane.

Cells tightly regulate their cholesterol content by (1) synthesis of cholesterol in the smooth endoplasmic reticulum (via the rate-limiting step hydroxymethylglutaryl-CoA [HMG-CoA] reductase), (2) receptor-mediated endocytosis of LDL (two mechanisms under the control of steroid-responsive element binding protein-2 [SREBP-2]), (3) efflux of cholesterol from the plasma membrane to cholesterol acceptor particles (predominantly apo A-I and HDL) via the ABCA1 and ABCG1 transporters, and (4) intracellular cholesterol

esterification via the enzyme acetyl-CoA acetyltransferase (ACAT) (Fig. 45-5A-C). SREBP-2 coordinately regulates the first two pathways at the level of gene transcription. Cellular cholesterol binds to SCAP (SREBP cholesterol-activated protein), which is localized on the endoplasmic reticulum. Cholesterol inhibits the interaction of SCAP with SREBP. In the absence of cholesterol, SCAP mediates the cleavage of SREBP at two sites by specific proteases with the release of an amino (NH₂) fragment of SREBP. The SREBP NH₂ fragment migrates to the nucleus and increases the transcriptional activity of genes involved in cellular cholesterol and fatty acid homeostasis. Cleavage of SREBP depends on a proprotein convertase related to the subtilisin/kexin family of convertases. Another member of the convertase superfamily, proprotein convertase subtilisin/kexin 9 (PCSK9), regulates the internalization and cellular processing of LDL-R; gain-of-function mutations in this gene cause autosomal dominant hypercholesterolemia, whereas loss-of-function mutations increase LDL-R and lower LDL-C significantly.⁸ The ACAT pathway regulates the cholesterol content in membranes. Humans express two separate forms of ACAT. ACAT1 and ACAT2 are derived from different genes and mediate cholesterol esterification in cytoplasm and in the endoplasmic reticulum lumen for lipoprotein assembly and secretion.

Regulation of cholesterol efflux from cells depends in part on the ABCA1 pathway, controlled in turn by hydroxysterols (especially 24- and 27-OH cholesterol, which act as ligands for the liver-specific receptor [LXR] family of transcriptional regulatory factors). In conditions of cholesterol sufficiency, the cell can decrease its input of cholesterol by decreasing the de novo synthesis of cholesterol. The

cell can also decrease the amount of cholesterol that enters the cell via the LDL-R, thereby increasing the amount stored as cholesteryl esters, and promote the removal of cholesterol by increasing its movement to the plasma membrane for efflux.

High-Density Lipoprotein and Reverse Cholesterol Transport

Epidemiologic studies have consistently shown an inverse relationship between plasma levels of HDL-C and the presence of CAD. HDL promotes reverse cholesterol transport and can prevent lipoprotein oxidation, exerts anti-inflammatory actions in vitro, and promotes cell proliferation and survival.⁹ In vitro, HDL has potent effects on vascular endothelial cells. It promotes the production of nitric oxide (NO) through several mechanisms and prevents the expression of vascular endothelial cell inflammatory mediators via modulation of nuclear factor kappa B (NF- κ B). Mendelian randomization analyses have cast doubt on HDL's causality as a protective cardiovascular risk factor. Mutations of the genes for ABCA1 (causing HDL deficiency) do not impart additional cardiovascular risk, and conversely, genetic polymorphisms of genes that increase HDL-C are not associated with protection from cardiovascular events.¹⁰

HDL has a complex and incompletely understood metabolism. The complexity arises because HDL particles acquire their components from several sources and these components undergo metabolism at different sites. In addition, steady-state levels of HDL in plasma may reflect the dynamic state of HDL-mediated cholesterol trafficking, in contrast to the situation with LDL. The intestine and liver synthesize apo A-I, the main protein of HDL. Approximately 80% of HDL originates from the liver and 20% from the intestine (Fig 45-4, path ⑤). Lipid-free apo A-I acquires phospholipids from cell membranes and from redundant phospholipids shed during the hydrolysis of TRLs. Lipid-free apo A-I binds to ABCA1 and promotes its phosphorylation via cAMP, which increases the net efflux of phospholipids and cholesterol onto apo A-I to form a nascent HDL particle (see Fig. 45-4, path ⑤). This particle contains apo A-I, phospholipids, and some free cholesterol (Fig. 45-5C).¹¹ These nascent HDL particles will mediate further cellular efflux of cholesterol. Currently, standard laboratory tests do not measure these HDL precursors because they contain little or no cholesterol. On reaching a cell membrane, the nascent HDL particles capture membrane-associated cholesterol and promote the efflux of free cholesterol onto other HDL particles (Fig. 45-4, path ⑩). Conceptually, the formation of HDL particles appears to involve two steps. The first step involves binding of HDL apo A-I to ABCA1 and generation of a specific membrane microdomain that allows the subsequent lipidation of apo A-I.¹² Efflux of cellular cholesterol from peripheral cells, such as macrophages, does not contribute importantly to overall HDL-C mass but may have an important effect on export of cholesterol from atheromas. Macrophages can transfer cholesterol to apo A-I and apo E, to nascent discoid or ellipsoid HDL particles via the ABCA1 transporter, or to more mature spherical HDL particles via the ABCG1 transporter (Fig 45-5D). The ABCG1 transporter does not promote cellular cholesterol efflux to lipid-free or lipid-poor apo A-I, but rather to mature HDL particles. HDL-mediated cellular cholesterol can be measured in plasma and is altered in many disease states, including diabetes and CAD.¹³ The plasma enzyme LCAT, an enzyme activated by apo A-I, then esterifies the free cholesterol (Fig. 45-4, path ⑧, and see Fig. 45-5C). LCAT transfers an acyl chain (a fatty acid) from the R₂ position of a phospholipid to the 3'-OH residue of cholesterol, which results in the formation of a cholesteryl ester (see Fig. 45-1). In a process called *selective uptake of cholesterol*, HDL also provides cholesterol to steroid hormone-producing tissues and the liver through the scavenger receptor SR-B1 (see Fig. 45-5B).

Because of their hydrophobicity, cholesteryl esters move to the core of the lipoprotein, and the HDL particle now assumes a spherical configuration (a particle denoted HDL₃). With further cholesterol esterification, the HDL particle increases in size to become the more buoyant HDL₂. The cholesterol within HDL particles can be exchanged with TRLs via CETP, which mediates an equimolar exchange of cholesterol from HDL to TRL and movement of

triglyceride from TRL onto HDL (see Fig. 45-4, path ⑨). Inhibition of CETP increases HDL-C in blood and has undergone exploration as a therapeutic target for prevention of CVD. PLTP mediates the transfer of phospholipids between TRL and HDL particles. Triglyceride-enriched HDLs are denoted HDL_{2b}. Hepatic lipase can hydrolyze triglycerides and endothelial lipase can hydrolyze phospholipids within these particles and thereby convert them back to HDL₃ particles.

Reverse cholesterol transport involves the uptake of cellular cholesterol from extrahepatic sources, such as lipid-laden macrophages, and its esterification by LCAT, transport by large HDL particles, and exchange for one triglyceride molecule by CETP. Hepatic receptors can now take up the cholesterol molecule originally on an HDL

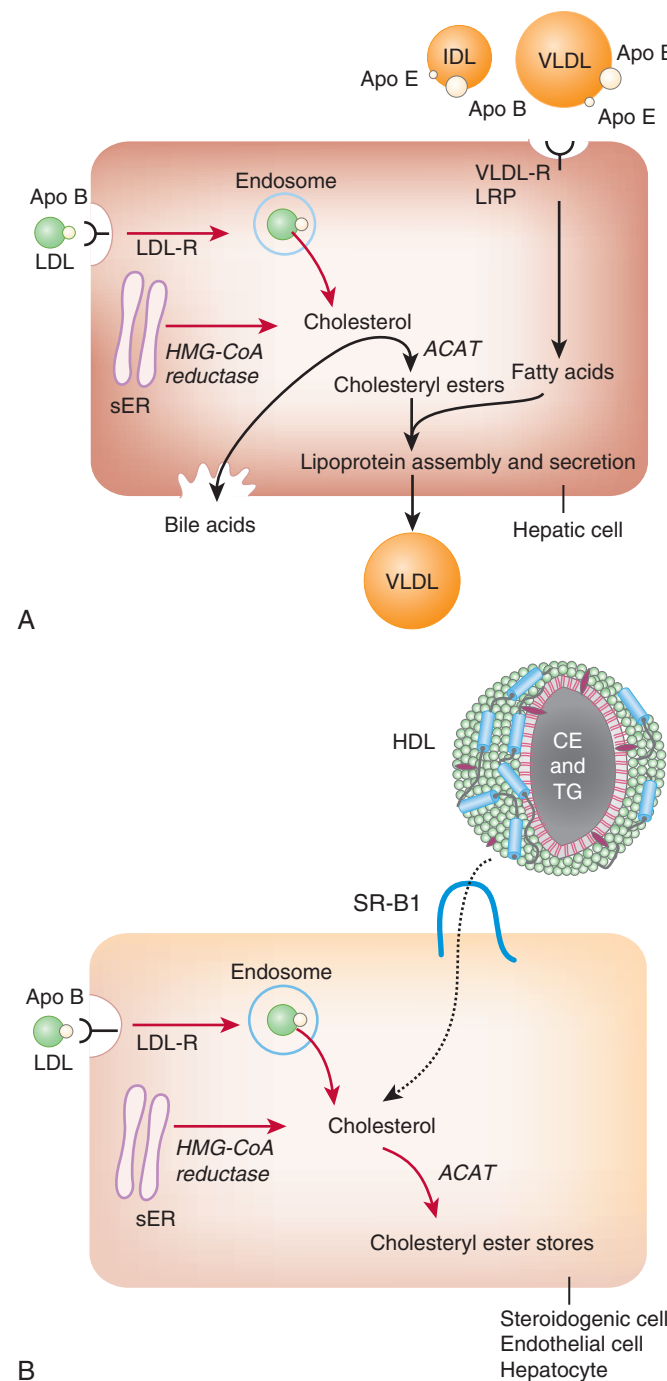

FIGURE 45-5 Cellular cholesterol homeostasis in various tissues. **A**, Cholesterol homeostasis (hepatocytes). **B**, Selective uptake of cholesterol (adrenal cells, hepatocytes, endothelial cells).

particle and residing in a TRL or LDL particle after this exchange. HDL particles therefore act as shuttles between tissue cholesterol, TRL, and the liver.

Reverse cholesterol transport by HDL constitutes a small but potentially important portion of the plasma HDL mass. Indeed, selective inactivation of macrophage ABCA1 does not change HDL-C levels in mice but increases atherosclerosis. The catabolism of HDL particles has engendered debate among lipoprotein researchers. The protein component of HDL particles is exchangeable with lipoproteins of other classes. The kidneys appear to be a route of elimination of apo A-I and other HDL apolipoproteins. The lipid components of HDL particles also follow a different metabolic route (Fig. 45-5B-D).

LIPOPROTEIN DISORDERS

Definitions

Time and new knowledge have stimulated changes in the classification of lipoprotein disorders. The original classification of lipoprotein disorders by Fredrickson, Lees, and Levy (1967) was based on measurement of total plasma cholesterol and triglycerides and analyzed lipoprotein patterns after separation by electrophoresis. This classification recognized elevations of chylomicrons (type I), VLDL or

pre-beta lipoproteins (type IV), beta lipoproteins (LDL) (type II), and both chylomicrons and VLDL (type V), as well as “broad beta” disease (or type III hyperlipoproteinemia). In addition, the combined elevation of pre-beta (VLDL) and beta (LDL) lipoproteins was recognized as type IIb hyperlipoproteinemia. Despite providing a useful conceptual framework, this classification has many drawbacks: it does not include HDL-C, and it does not differentiate severe monogenic lipoprotein disorders from the more common polygenic disorders. Subsequently, the World Health Organization, the European Atherosclerosis Society, and more recently, the National Cholesterol Education Program (NCEP) classified lipoprotein disorders on the basis of arbitrary cut points.

A practical approach describes the lipoprotein disorder by the absolute plasma levels of lipids (cholesterol and triglycerides) and lipoprotein cholesterol levels (LDL-C and HDL-C) and considers clinical manifestations of hyperlipoproteinemia in the context of biochemical characterization. For example, a young patient with eruptive xanthomas and a plasma triglyceride level of 11.3 mmol/L (1000 mg/dL) probably has familial hyperchylomicronemia as a result of LPL deficiency or other genetic defects. An obese, hypertensive middle-aged man with a cholesterol level of 6.4 mmol/L (245 mg/dL), a triglyceride level of 3.1 mmol/L (274 mg/dL), an HDL-C level of 0.8 mmol/L (31 mg/dL), and a calculated LDL-C level of 4.2 mmol/L (162 mg/dL) probably has metabolic syndrome, and this should trigger the clinician to seek other components of this cluster, including hypertension and hyperglycemia. Conversely, an obese middle-aged man with a plasma triglyceride level of 7 mmol/L (620 mg/dL) probably has

mutations in several genes associated with plasma triglyceride levels.¹⁴

The clinical usefulness of apolipoprotein levels has stirred debate (see also Chapter 42). Taken as a single measurement, the apo B level provides information on the number of potentially atherogenic particles and can be used as a goal of lipid-lowering therapy. Similarly, LDL particle size correlates highly with plasma HDL-C and triglyceride levels, and most studies do not show it to be an independent cardiovascular risk factor. Small, dense LDL particles tend to track with features of metabolic syndrome, which usually involves dyslipoproteinemia with elevated plasma triglyceride and reduced HDL-C levels. The Emerging Risk Factors Collaboration studies have shown that measurement of non-HDL-C is equivalent to measurement of apo B in determination of cardiovascular risk. Indeed, measurement of non-HDL-C captures the cholesterol content in apo B-containing lipoproteins. Similarly, HDL-C tracks as well with CVD risk as apo A-I does.¹⁵ Such observations prompted a joint statement from the American Heart Association and the American College of Cardiology on the lack of incremental values of apolipoprotein measurement or lipoprotein particle size in predicting cardiovascular risk.¹⁶

Genetic Lipoprotein Disorders

Understanding of the genetics of lipoprotein metabolism has expanded rapidly. Classification of genetic lipoprotein disorders

usually requires a biochemical phenotype in addition to a clinical phenotype. With the exception of familial hypercholesterolemia (FH), monogenic disorders tend to be infrequent or very rare. Disorders considered heritable on careful family study may be difficult to characterize unambiguously because of age, sex, penetrance, and gene-gene and environmental interactions. Most common lipoprotein disorders encountered clinically result from the interaction of increasing age, lack of physical exercise, weight gain, and a suboptimal diet with individual genetic makeup. Genetic lipoprotein disorders can either raise or lower levels of LDL, Lp(a), remnant lipoproteins, TRLs (chylomicrons and VLDL), or HDL (**Table 45-4**).

Low-Density Lipoproteins (Type II Hyperlipidemia) Autosomal Dominant Hypercholesterolemia (Familial Hypercholesterolemia)

FH is the most thoroughly studied lipoprotein disorder. Elucidation of the pathway by which complex molecules enter the cell by receptor-mediated endocytosis and discovery of LDL-R represent landmarks in cell biology and clinical investigation. Affected subjects have an elevated LDL-C level greater than the 95th percentile for age and sex. In adulthood, clinical manifestations include corneal arcus, tendinous xanthomas over the extensor tendons (metacarpophalangeal joints, patellar, triceps, and Achilles tendons), and xanthelasmas. Transmission is autosomal codominant. FH affects approximately 1

in 500, although this prevalence is higher in populations with a founder effect. Patients with FH have high risk for the development of CAD by the third to fourth decade in men and approximately 8 to 10 years later in women. Diagnosis is based on an elevated plasma LDL-C level, family history of premature CAD, and the presence of xanthomas.¹⁷

LOW-DENSITY LIPOPROTEIN RECEPTOR GENE. Defects in the *LDLR* gene cause an accumulation of LDL particles in plasma and thus alter the function of the LDL-R protein and cause FH (see **Fig. 45-4**, path ⑦). Well in excess of 1000 mutations of the *LDLR* gene can cause FH.

FAMILIAL DEFECTIVE APOLOPROTEIN B. Mutations within the *APOB* gene that lead to an abnormal ligand-receptor interaction can cause a form of autosomal dominant hypercholesterolemia clinically indistinguishable from FH. Several mutations at the postulated binding site to LDL-R cause familial defective apo B100 (see **Fig. 45-4**, path ⑦). These consist of apo B_{Arg3500Gln}, apo B_{Arg3500Trp}, and apo B_{Arg3531Cys}. Apo B_{Arg3500Gln} results from a G → A substitution at nucleotide 3500 within exon 26 of the *APOB* gene. The defective apo B has reduced affinity (20% to 30% of control) for LDL-R. LDL particles with defective apo B have a plasma half-life threefold to fourfold greater than the half-life of normal LDL. Because of their increased persistence, these LDL particles can more readily undergo oxidative modifications that can enhance their atherogenicity. Affected subjects usually have LDL-C levels elevated up to 400 mg/dL (10.4 mmol/L) but may also have normal levels. Familial defective apo B100 has a prevalence similar to that of FH (1 in 500). In subjects with the classic manifestation of FH, the prevalence of familial defective apo B100 is reported to be 1 in 50 to 1 in 20. Reasons for the variability in plasma LDL-C levels remain unexplained.

PROTEIN CONVERTASE, SUBTILISIN/KEXIN TYPE 9 GENE.

An autosomal dominant form of hypercholesterolemia that maps to chromosome 1p34.1 involves a mutation within the *PCSK9* gene. *PCSK9* codes for a proprotein convertase belonging to the subtilase family of convertases. It is related to subtilisin/kexin isoenzyme-1 (site-1 protease), which is required for the cleavage of SREBP. PCSK9 binds to the epidermal growth factor homology domain of LDL-R on the cell membrane, and the internalized LDL-R-PCSK9 complex enters the cell and undergoes lysosomal degradation. Thus gain-of-function mutations in the *PCSK9* gene decrease surface availability of the LDL-R protein and cause accumulation of LDL-C in plasma. Subjects with a loss-of-function mutation of *PCSK9* have markedly lower LDL-C than do subjects without the mutation. Black Americans had a higher prevalence of this protective mutation than did whites in the ARIC (Atherosclerosis Risk in Communities) study, and subjects with life-long low LDL-C because of a mutation at the *PCSK9* gene locus had a marked reduction in coronary events,¹⁸ thus confirming that genetically low LDL-C states lower cardiovascular risk.

PCSK9 has appeal as a therapeutic target. Small-molecule inhibition has not succeeded in blocking PCSK9 function. Parenteral administration of injectable, humanized monoclonal antibodies directed against PCSK9 has markedly reduced LDL-C in humans and will undergo evaluation in clinical endpoint trials.^{19,20}

Autosomal Recessive Hypercholesterolemia

An autosomal recessive form of FH identified in a kindred from Sardinia results from a mutation in the gene coding for the LDL-R adaptor protein (*LDL-RAP-1* gene), which encodes a protein involved in recycling of LDL-R.

HYPOBETALIPOPROTEINEMIA AND ABETALIPOPROTEINEMIA.

Mutations within the *APOB* gene can lead to truncations of the mature apo B100 peptide. Many such mutations cause a syndrome characterized by reduced LDL-C and VLDL-C but little or no clinical manifestations and no known risk for CVD, a condition referred to as hypobetalipoproteinemia. Apo B truncated close to its amino-terminal loses the ability to bind lipids, thereby producing a syndrome similar to abetalipoproteinemia, a rare recessive lipoprotein disorder of infancy that causes mental retardation and growth abnormalities. Abetalipoproteinemia results from a mutation in the gene coding for the microsomal triglyceride transfer protein (MTP), which

TABLE 45-4 Genetic Lipoprotein Disorders

is required for assembly of apo B-containing lipoproteins in the liver and the intestine. The resulting lack of apo B-containing lipoproteins in plasma causes a marked deficiency of fat-soluble vitamins (A, D, E, and K) that circulate in lipoproteins. In turn, this results in mental and developmental retardation in affected children.

SITOSTEROLEMIA. A rare condition of increased intestinal absorption and decreased excretion of plant sterols (sitosterol and campesterol) can mimic severe FH with extensive xanthoma formation. Premature atherosclerosis, often apparent clinically well before adulthood, occurs in patients with sitosterolemia. Diagnosis requires specialized analysis of plasma sterols in which an elevation in sitosterol, campesterol, cholestanol, sitostanol, and campestanol is demonstrated. Interestingly, plasma cholesterol levels are normal or reduced, and triglyceride levels are normal. Patients with sitosterolemia have homozygous (or compound heterozygous) mutations in the *ABCG5* and *ABCG8* genes. The gene products of *ABCG5* and *ABCG8* are half ABC transporters and form a heterodimer characteristic of the full ABC transporters. The complex, located in the villous border of intestinal cells, actively pumps plant sterols back into the intestinal lumen. A defect in either of the genes inactivates this transport mechanism, and net accumulation of plant sterols (because of impaired elimination) ensues. *ABCG5* and *ABCG8* mutations leading to sitosterolemia are very rare.

Lipoprotein(a)

Lp(a) (pronounced “lipoprotein little a”) consists of an LDL particle linked covalently with one molecule of apo (a). The apo (a) moiety consists of a protein with a high degree of homology with plasminogen. The gene for apo (a) appears to have arisen from the plasminogen gene by nonhomologous recombination. The apo (a) gene has multiple repeats of one of the kringle motifs (kringle IV), which vary in number from 12 to more than 40 in each individual. Plasma Lp(a) levels depend almost entirely on genetics and correlate inversely with the number of kringle repeats and therefore with the molecular weight of apo (a). Mendelian randomization data from the Copenhagen Heart Study implicated Lp(a) as a genetically determined cardiovascular risk factor.²¹ Lp(a) concentrations follow a skewed distribution in the population, and black Americans tend to have higher Lp(a) levels than do other ethnic groups in the United States. Few environmental factors or medications modulate plasma Lp(a) levels. The pathogenesis of Lp(a) may result from an antifibrinolytic potential and/or ability to bind oxidized lipoproteins. Some prospective epidemiologic studies have shown a positive (albeit weak) association between Lp(a) and CAD.

Triglyceride-Rich Lipoproteins

In subjects with metabolic syndrome and in diabetic patients, elevation of plasma triglyceride levels occurs most often in the presence of visceral (abdominal) obesity and a diet rich in calories, carbohydrates, and saturated fats. Severe elevation of plasma triglycerides can result from genetic disorders of the processing enzymes or apolipoproteins and poorly controlled diabetes.

Familial Hypertriglyceridemia (Type IV Hyperlipoproteinemia)

Familial hypertriglyceridemia is not associated with clinical signs such as corneal arcus, xanthoma, and xanthelasmas. Plasma triglycerides, VLDL-C, and VLDL triglycerides are moderately to markedly elevated; the LDL-C level is usually low, as is HDL-C. Total cholesterol is normal or elevated, depending on VLDL-C levels. Fasting plasma concentrations of triglycerides are in the range of 2.3 to 5.7 mmol/L (200 to 500 mg/dL). After a meal, plasma triglycerides may exceed 11.3 mmol/L (1000 mg/dL). The disorder is found in first-degree relatives, but phenotypic variability is related to sex, age, hormone use (especially estrogens), and diet. Alcohol intake potentially stimulates hypertriglyceridemia in these subjects, as does caloric or carbohydrate intake. Familial hypertriglyceridemia has a weaker relationship with CAD than familial combined hyperlipidemia does, and not all studies support this association. Depending on the criteria used, the

prevalence of familial hypertriglyceridemia ranges from 1 in 100 to 1 in 50. This highly heterogeneous disorder probably results from several genes, as well as a strong environmental influence. An unrelated disorder, familial glycerolemia, a chromosome X-linked genetic disorder, may mimic familial hypertriglyceridemia because most measurement techniques for triglycerides use the measurement of glycerol after enzymatic hydrolysis of triglycerides. Diagnosis of familial hyperglycerolemia requires ultracentrifugation of plasma and analysis of glycerol.

Hepatic overproduction of VLDL causes familial hypertriglyceridemia (see Fig. 45-4, path ④); the catabolism (uptake) of VLDL particles can be normal or reduced. Lipolysis by LPL does not appear to be limiting under basal conditions, but excess triglyceride load, especially following fatty meals, may lead to impaired processing of VLDL particles. The genetic basis of familial hypertriglyceridemia has recently been elucidated further. Using data derived from genome-wide association studies, Hegele and colleagues have shown that many cases of severe hypertriglyceridemia are due to mutations in one or more of the genes associated with triglyceride metabolism.¹⁴ Treatment is based first on lifestyle modifications, including withdrawal of hormones (estrogens and progesterone), limiting alcohol intake, reducing caloric intake, and increasing exercise. The decision to treat this disorder with medications (see later) depends on global cardiovascular risk.

An infrequent disorder characterized by a severe elevation in plasma triglyceride levels (both VLDL and chylomicrons) is associated with a fat-rich diet, obesity, and poorly controlled diabetes. Recognized as type V hyperlipidemia, the pathogenesis is multifactorial and results from overproduction of both VLDL and chylomicrons and decreased catabolism of these particles.

Familial Hyperchylomicronemia (Type I Hyperlipidemia)

This rare disorder of severe hypertriglyceridemia is associated with elevations in fasting plasma triglycerides to greater than 11.3 mmol/L (>1000 mg/dL). These patients have recurrent bouts of pancreatitis and eruptive xanthomas. Interestingly, severe hypertriglyceridemia can also be associated with xerostomia, xerophthalmia, and behavioral abnormalities. The hypertriglyceridemia results from markedly reduced or absent LPL activity or, more rarely, absence of its activator apo C-II (see Fig. 45-4, path ②). These defects lead to a lack of hydrolysis of chylomicrons and VLDL and their accumulation in plasma, especially after meals. Extreme elevations of plasma triglycerides (>113 mmol/L; >10,000 mg/dL) can result. As stated earlier, the cumulative effects of mutations at several genes associated with triglyceride metabolism can result in elevated chylomicrons.

Plasma from a patient with very high triglyceride levels is milky white, and a clear band of chylomicrons can be seen on top of the plasma after it stands overnight in a refrigerator. Populations with a founder effect can have high prevalence of LPL mutations. At least 60 LPL mutations can cause LPL deficiency. LPL₁₈₈, LPL_{asn291ser}, and LPL₂₀₇ are frequently associated with hyperchylomicronemia. Heterozygotes for the disorder tend to have an increase in fasting plasma triglycerides and smaller, denser LDL particles. Many patients with complete LPL deficiency exhibit failure to thrive in childhood and have recurrent bouts of pancreatitis. To underscore the importance of the role of LPL, *lpl* deficiency in the mouse leads to a perinatal lethal phenotype. Treatment of acute pancreatitis includes intravenous hydration and avoidance of fat in the diet (including fat in parenteral nutrition). Plasma filtration is required only rarely. Chronic treatment includes avoidance of alcohol and dietary fat. Addition of short-chain fatty acids (which are not incorporated in chylomicrons) can increase palatability of the diet.

Type III Hyperlipoproteinemia

Type III hyperlipoproteinemia, also referred to as *dysbetalipoproteinemia* or *broad beta disease*, is a rare genetic lipoprotein disorder characterized by accumulation of remnant lipoprotein particles in plasma. Lipoprotein agarose gel electrophoresis shows a typical pattern of a broad band between the pre-beta (VLDL) and beta (LDL) lipoproteins,

hence the name “broad beta disease.” Patients with this disease have increased cardiovascular risk. Clinical findings consist of pathognomonic tuberous xanthomas and palmar striated xanthomas. The lipoprotein profile shows increased cholesterol and triglyceride levels and reduced HDL-C. Remnant lipoproteins (partly catabolized chylomicrons and VLDL) accumulate in plasma and become enriched with cholesterol esters. The defect results from abnormal apo E, which does not bind to hepatic receptors that recognize apo E as a ligand (see Fig. 45-4, path ③). The ratio of VLDL cholesterol to triglycerides, normally less than 0.7 (when measured in mmol/L; <0.30 in mg/dL), is elevated in patients with type III hyperlipoproteinemia because of cholesteryl ester enrichment of remnant particles. Thus calculation of LDL-C in such patients is unreliable, and direct LDL-C measurement may be required for clinical purposes. Diagnosis includes plasma ultracentrifugation for lipoprotein separation, lipoprotein electrophoresis, and apo E phenotyping or genotyping. Patients with type III hyperlipoproteinemia have the apo E_{2/2} phenotype or genotype. Apo E has three common alleles: E₂, E₃, and E₄. The apo E₂ allele has markedly decreased binding to the apo B/E receptor.

The apo E_{2/2} genotype has a prevalence of approximately 0.7% to 1.0%. Type III hyperlipoproteinemia occurs in approximately 1% of subjects bearing the apo E_{2/2} genotype. Reasons for the relative rarity of type III dyslipoproteinemia are not fully understood. Mutations in other genes associated with triglyceride metabolism contribute to phenotypic expression of the apo E_{2/2} genotype.¹⁴ Other rare mutations of the gene for apo E can cause type III hyperlipoproteinemia. In general, type III dyslipoproteinemia responds well to dietary therapy, correction of other metabolic abnormalities (diabetes, obesity, hypothyroidism), and in cases requiring drug therapy, use of fibric acid derivatives or statins. The importance of the apo E gene and protein is underscored by the widespread use of the apo E-deficient mouse, in which experimental atherosclerosis develops.

Familial Combined Hyperlipidemia

Familial combined hyperlipoproteinemia is one of the most common familial lipoprotein disorders. Described initially in survivors of myocardial infarction, the definition of familial combined hyperlipoproteinemia has undergone several refinements. It is characterized by the presence of elevated total cholesterol and/or triglyceride levels based on arbitrary cut points in several members of the same family. Advances in analytic techniques have added measurement of LDL-C and, in some cases, apo B levels. Because of the lack of a clear-cut clinical or biochemical marker, considerable overlap exists between familial combined hyperlipoproteinemia, familial dyslipidemic hypertension, metabolic syndrome, and hyperapobetalipoproteinemia. Genetic heterogeneity probably underlies familial combined hyperlipoproteinemia, which has a prevalence of approximately 1 in 50 and accounts for 10% to 20% of patients with premature CAD. The condition has few clinical signs; corneal arcus, xanthomas, and xanthelasma occur infrequently. Biochemical abnormalities include elevation of plasma total cholesterol and LDL-C levels (>90th to 95th percentile) and/or elevation of plasma triglycerides (>90th to 95th percentile)—a type IIb lipoprotein phenotype, often in correlation with low HDL-C and elevated apo B levels; small, dense LDL particles occur frequently. Diagnosis of familial combined hyperlipoproteinemia requires identification of the disorder in at least one first-degree relative. Underlying metabolic disorders appear to include hepatic overproduction of apo B-containing lipoproteins, delayed postprandial clearance of TRLs, and increased flux of FFAs to the liver.

Experimental data have shown that substrate levels drive hepatic apo B secretion, the most important substrates being FFAs and cholesteryl esters. Increased delivery of FFAs to the liver, as occurs in states of insulin resistance and visceral obesity, leads to increased hepatic apo B secretion. Familial combined hyperlipoproteinemia has complex genetics. It was initially considered an autosomal codominant trait; modifying factors include sex, age at onset, and comorbid states such as obesity, lack of exercise, and diet. Novel loci in the upstream transcription factor 1 (*USF1*) and stearoyl-CoA desaturase 1 genes are promising candidate genes related to familial combined hyperlipoproteinemia.²²

High-Density Lipoproteins

Reduced plasma levels of HDL-C consistently correlate with the development or presence of CAD. Most cases of reduced HDL-C result from elevated plasma triglycerides or apo B levels and often keep company with other features of metabolic syndrome. Primary forms of reduced HDL-C that occur in cases of premature CAD have helped shed light on the complex metabolism of HDL particles. Genetic disorders of HDL can result from decreased production or abnormal maturation and increased catabolism. Genetic lipoprotein disorders leading to moderate to severe elevations in plasma triglycerides cause a reduction in HDL-C levels. Familial hyperchylomicronemia, familial hypertriglyceridemia, and familial combined hyperlipoproteinemia are all associated with reduced HDL-C levels. In complex disorders of lipoprotein metabolism such as familial combined hyperlipidemia, metabolic syndrome, and common forms of hypertriglyceridemia, several factors most likely correlate with low HDL-C level. Plasma triglyceride and HDL-C levels vary inversely. There are several reasons for this association: (1) decreased lipolysis of TRLs decreases the availability of substrate (phospholipids) for HDL maturation, (2) HDL enriched with triglyceride has an increased catabolic rate and hence reduced plasma concentration, and (3) the augmented pool of TRLs saps cholesterol from the HDL compartment by CETP-mediated exchange.

Disorders of High-Density Lipoprotein Biogenesis^{12,23}

Apolipoprotein A-I Gene Defects

Primary defects affecting the production of HDL particles may be caused by mutations in the apo A-I–C-III–A-IV gene complex. More than 46 mutations affect the structure of apo A-I and lead to a marked reduction in HDL-C levels. Not all these defects are associated with premature CVD. Clinical findings can vary from extensive atypical xanthomatosis and corneal infiltration of lipids to no manifestations at all. Treatment of these apo A-I gene defects generally fails to raise HDL-C levels. Other mutations of apo A-I lead to an increased catabolic rate of apo A-I and may not be associated with CVD. One such mutation, apo A-I^{Milano} (apo A-I_{Arg173Cys}), appears to not increase risk for CVD despite very low HDL levels.

Tangier Disease and Familial High-Density Lipoprotein Deficiency

A rare disorder of HDL deficiency was identified in a proband from the Chesapeake Bay island of Tangier in the United States. The proband, whose sister was also affected, had markedly enlarged yellow tonsils and nearly absent HDL-C levels, an entity now called *Tangier disease*. The cellular defect in Tangier disease consists of reduced cellular cholesterol efflux in skin fibroblasts and macrophages from affected subjects. A more common entity, familial HDL deficiency, was also found to result from decreased cellular cholesterol. Tangier disease and familial HDL deficiency result from mutations in the *ABCA1* gene, which encodes the ABCA1 transporter (see Fig. 45-5C). More than 200 mutations in *ABCA1* have been reported to cause Tangier disease (homozygous or compound heterozygous mutations) or familial HDL deficiency (heterozygous mutations). Subjects with Tangier disease and familial HDL deficiency may have an increased risk for CAD, counterbalanced by their very low levels of LDL-C, which may exert a protective effect. Mendelian randomization analysis has not supported a causal relationship between mutations in the *ABCA1* gene and CAD in the Copenhagen Heart Study. ABCA1 appears to shuttle from the late endosomal compartment to the plasma membrane and act as a membrane-bound transporter of phospholipids (and cholesterol) onto acceptor proteins such as apo A-I and apo E. Hydroxysterols regulate ABCA1 via the LXR/retinoid X receptor (RXR) nuclear receptor pathway. ABCA1 undergoes phosphorylation via protein kinase A and acts as a receptor for apo A-I.

Niemann-Pick type C disease is a disorder of lysosomal cholesterol transport. In patients with Niemann-Pick type C disease, mental retardation and neurologic manifestations occur frequently. The cellular phenotype involves markedly decreased cholesterol esterification and a defect in the cellular transport of cholesterol to the Golgi apparatus. Unlike Tangier disease/familial HDL deficiency, the cellular defect in

Niemann-Pick type C disease appears to be proximal to the transport of cholesterol to the plasma membrane. The gene for Niemann-Pick type C disease (*NPC1*) has been mapped to 18q21, and the gene codes for a 1278–amino acid protein, which appears to be involved in shuttling of cholesterol between the late endosomal pathway and the plasma membrane. The NPC1 gene product shares homology with the morphogen receptor *patched* and SCAP. Niemann-Pick type C cells lack NPC1 protein; cholesterol sequestration within the late endosome compartment prevents upregulation of ABCA1, and these patients thus have impaired cellular cholesterol efflux and HDL assembly.

Disorders of High-Density Lipoprotein–Processing Enzymes

Lecithin-Cholesterol Acyltransferase Deficiency

Genetic defects in the HDL-processing enzymes give rise to interesting phenotypes. Deficiencies of LCAT, the enzyme that catalyzes the formation of cholesteryl esters in plasma, cause corneal infiltration of neutral lipids and hematologic abnormalities as a result of the abnormal constitution of red blood cell membranes. LCAT deficiency can lead to an entity called “fish eye disease” because of the characteristic pattern of corneal infiltration observed in affected individuals. Despite the profound HDL-C deficiency, LCAT deficiency does not appear to increase risk for CAD.

Cholesteryl Ester Transfer Protein Deficiency

Patients without CETP have very elevated levels of HDL-C, which is enriched in cholesteryl esters. Because CETP facilitates the transfer of HDL cholesteryl esters into TRLs, a deficiency of this enzyme causes accumulation of cholesteryl esters within HDL particles. CETP deficiency is not associated with premature CAD but may not afford protection against CAD. Because of its effects on HDL-C, CETP inhibition has received considerable attention as a therapeutic target for the treatment of lipoprotein disorders. Despite some disappointing clinical results, currently ongoing clinical trials of CETP inhibitors continue to assess this approach (see later).

Niemann-Pick type I disease (subtypes A and B), which is caused by mutations in the sphingomyelin phosphodiesterase-1 (*SMPD1*) gene, is associated with a low HDL-C level. The *SMPD1* gene encodes a lysosomal (acidic) and secretory sphingomyelinase. The low HDL-C level in patients with Niemann-Pick A and B disease appears to result from a decrease in LCAT reaction because of abnormal HDL constituents.

Recent genome-wide association studies have identified multiple gene loci associated with plasma lipid levels, thus raising the possibility of identifying novel pathways in lipoprotein metabolism and potential novel therapeutic targets.²⁴

Secondary Causes of Hyperlipidemia and Metabolic Syndrome

Several clinical disorders lead to alterations in lipoprotein status (Table 45-5).

Hormonal Causes

Hypothyroidism, a not infrequent cause of secondary lipoprotein disorders, is often manifested as elevated LDL-C, triglycerides, or both (see also Chapter 81). An elevated level of thyroid-stimulating hormone (TSH) provides the key to the diagnosis, and the lipoprotein abnormalities often revert to normal after correction of thyroid status. Rarely, hypothyroidism may uncover a genetic lipoprotein disorder such as type III hyperlipidemia. Estrogens can elevate plasma triglyceride and HDL-C levels, probably because of increases in both hepatic VLDL and apo A-I production. In postmenopausal women, estrogens may reduce LDL-C by up to 15%. Use of estrogens for the treatment of lipoprotein disorders is no longer recommended because of the slight increase in cardiovascular risk with prolonged use of estrogens in the postmenopausal period (see also Chapter 77). Rarely, pregnancy causes severe increases in plasma triglycerides on a background of LPL deficiency or yet to be identified genetic defects. Such cases present a serious threat to mother and child and require referral to specialized centers. Male sex hormones and anabolic

TABLE 45-5 Secondary Causes of Dyslipoproteinemias

CAUSE	DISORDER
Metabolic	Diabetes Lipodystrophy Glycogen storage disorders
Renal	Chronic renal failure Glomerulonephritis with nephritic syndrome
Hepatic	Cirrhosis Biliary obstruction Porphyria Primary biliary cirrhosis (with secondary LCAT deficiency)
Hormonal	Estrogens Progesterones Growth hormone Thyroid disorders (hypothyroidism) Corticosteroids
Lifestyle	Physical inactivity Obesity Diet rich in fats, saturated fats Alcohol intake Smoking
Medications	Retinoic acid derivatives Glucocorticoids Exogenous estrogens Thiazide diuretics Beta-adrenergic blocking agents (selective) Testosterone and other anabolizing steroids Immunosuppressive medications (cyclosporine) Antiviral medications (human immunodeficiency virus protease inhibitors) Antischizophrenic medications

steroids can increase hepatic lipase activity and have been used for the treatment of hypertriglyceridemia in men; however, these agents can also contribute to an elevated triglyceride level, reduced HDL-C, increased blood pressure, and other features of metabolic syndrome. Growth hormone can reduce LDL-C and increase HDL-C but is not recommended for the treatment of lipoprotein disorders.

Metabolic Causes

The most frequent secondary cause of dyslipoproteinemia is probably the constellation of metabolic abnormalities seen in patients with metabolic syndrome. The finding of increased visceral fat (abdominal obesity), elevated blood pressure, and impaired glucose tolerance often clusters with increased plasma triglycerides and a reduced HDL-C level and represents the major components of metabolic syndrome (see also Chapters 42 and 61). Overt diabetes, especially type 2 diabetes, frequently elevates plasma triglycerides and reduces HDL-C. These abnormalities have prognostic implications in patients with type 2 diabetes. Poor control of diabetes, obesity, and moderate to severe hyperglycemia can yield severe hypertriglyceridemia with chylomicronemia and increased VLDL-C levels. Subjects with poorly controlled type 1 diabetes can also have severe hypertriglyceridemia. Familial lipodystrophy (complete or partial) may be associated with increased VLDL secretion. Dunnigan lipodystrophy, a genetic disorder with features of metabolic syndrome, results from mutations within the lamin A/C gene and is associated with limb-girdle fat atrophy. Excess plasma triglycerides often accompany glycogen storage disorders.

Renal Disorders

In subjects with glomerulonephritis and protein-losing nephropathies (see also Chapter 88), a marked increase in secretion of hepatic lipoproteins can raise LDL-C levels, which may approach the levels seen in subjects with FH. By contrast, patients with chronic renal failure have a pattern of hypertriglyceridemia with reduced HDL-C. Patients with end-stage renal disease, including those undergoing hemodialysis or chronic ambulatory peritoneal dialysis, have a poor prognosis and accelerated atherosclerosis. Recent trials of statins in

diabetic patients undergoing dialysis in which no reduction in cardiovascular endpoints was shown have challenged the use of statins in such patients with end-stage renal disease. After organ transplantation, the immunosuppressive regimen (glucocorticoids and cyclosporine) typically elevates triglycerides and reduces HDL-C levels. Because transplant recipients generally have an increase in cardiovascular risk, this secondary hyperlipidemia may warrant treatment. Patients receiving the combination of a statin plus cyclosporine merit careful dose titrations and monitoring for myopathy.

Liver Disease

Obstructive liver disease, especially primary biliary cirrhosis, may lead to the formation of an abnormal lipoprotein termed *lipoprotein-x*. This type of lipoprotein, also associated with LCAT deficiency, consists of an LDL-like particle with a marked reduction in cholesteryl esters. Extensive xanthoma formation on the face and palmar areas can result from accumulation of lipoprotein-x.

Lifestyle

Factors contributing to obesity, such as an imbalance between caloric intake and energy expenditure, lack of physical activity, and a diet rich in saturated fats and refined sugars, contribute in large part to the lipid and lipoprotein lipid levels within a population (see also Chapter 42).

Medication

Several medications can alter lipoproteins. Thiazide diuretics can increase plasma triglyceride levels. Beta-adrenergic blocking agents (beta blockers), especially non-beta-selective agents, increase triglycerides and lower HDL-C levels. Retinoic acid and estrogens can increase triglyceride levels, sometimes dramatically. Corticosteroids and immunosuppressive agents can increase plasma triglyceride levels and lower HDL-C levels. Estrogens can increase plasma HDL-C significantly and often increase triglyceride concentrations. Anabolic steroids, frequently used by endurance or body-building athletes, can cause hypertriglyceridemia and very low HDL-C. The exact composition, dosage, and frequency of use of anabolic steroids are often impossible to gather from the patient. The use of second-generation antipsychotic medications may lead to metabolic disorders, weight gain, and lipoprotein abnormalities.²⁵ The use of highly active antiretroviral agents may cause severe lipoprotein disorders and an increase in the prevalence of CAD in patients with chronic human immunodeficiency virus infection treated with such agents (see also Chapter 70).²⁶

In clinical practice, many dyslipoproteinemias, other than the genetic forms mentioned earlier, share an important environmental cause. Lifestyle changes (diet, exercise, reduction of abdominal obesity) should form the foundation for the treatment of most dyslipidemias. The effects of marked alterations in lifestyle, reduction in dietary fats, especially saturated fats, and exercise can improve cardiovascular risk factors. Rigorous clinical data showing that these measures improve outcomes and implementing them in a sustained manner in practice, however, have proved more difficult.

PHARMACOLOGIC MANAGEMENT OF LIPID RISK (TABLE 45-6)

Bile Acid–Binding Resins

Bile acid–binding resins interrupt the enterohepatic circulation of bile acids by inhibiting their reabsorption in the intestine (the site of reabsorption of more than 90% of bile acids). Currently, their main use is adjunctive therapy in patients with severe hypercholesterolemia secondary to increased LDL-C. Because bile acid–binding resins are not absorbed systemically (they remain in the intestine and are eliminated in stool), they are considered safe in children. Cholestyramine (Questran) is used in 4-g unit doses as a powder, and colestipol (Colestid) is used in 5-g unit doses. Effective doses range from 2 to 6 unit doses/day, always taken with meals. The most important side effects are predominantly gastrointestinal:

TABLE 45-6 Current Lipid-Lowering Medications

GENERIC NAME	TRADE NAME	RECOMMENDED DOSE RANGE
Statins		
Atorvastatin	Lipitor	10-80 mg
Fluvastatin	Lescol	20-80 mg
Lovastatin	Mevacor	20-80 mg
Pravastatin	Pravachol	10-40 mg
Rosuvastatin	Crestor	10-40 mg
Simvastatin	Zocor	10-80 mg
Pitavastatin	Livalo	2-4 mg
Bile Acid Absorption Inhibitors		
Cholestyramine	Questran	2-24 g
Colestipol	Colestid	5-30 g
Colesevelam	WelChol	3.8-4.5 g
Cholesterol Absorption Inhibitors		
Ezetimibe	Zetia (Ezetrol)	10 mg
Fibrates*		
Bezafibrate	Bezalip	400 mg
Fenofibrate	Tricor, Trilipix Lipidil (Micro, EZ)	40-200 mg
Gemfibrozil†	Lopid	600-1200 mg
Niacin‡		
Niacin	Niaspan	1-3 g
Nicotinic acid	Niaspan	1-2 g

*Avoid in patients with renal insufficiency.

†Not recommended in combination with statins.

‡Use with caution in patients with diabetes or glucose intolerance.

constipation, a sensation of fullness, and gastrointestinal discomfort. These drugs can cause hypertriglyceridemia. Decreased absorption of concomitantly administered drugs dictates careful scheduling of other medications 1 hour before or 4 hours after the patient takes bile acid–binding resins. Bile acid–binding resins can be used in combination with statins and/or cholesterol absorption inhibitors in cases of severe hypercholesterolemia. Colesevelam is a bioengineered bile acid–binding resin that has roughly twice the capacity to bind cholesterol as cholestyramine does. In doses of 3.8 to 4.5 g/day, it can be a useful third-line therapy for patients not meeting their LDL-C targets or in whom the side effects of statins preclude their optimal use. Colesevelam can also decrease glycated hemoglobin A1c (HbA1c), thus making this drug a potentially useful adjunct in the treatment of complicated diabetic patients. Even though relatively few drug-drug interactions have been reported with colesevelam, prudence still warrants a careful dosage schedule (4 hours), which makes the use of all bile acid–binding resins cumbersome in patients taking multiple medications.

Hydroxymethylglutaryl–Coenzyme A Reductase Inhibitors (Statins)

Mechanisms of Action

Statins inhibit the enzyme HMG-CoA reductase and prevent the formation of mevalonate, the rate-limiting step of sterol synthesis. To maintain cellular cholesterol homeostasis, expression of LDL-R increases and the rate of cholesteryl ester formation declines. These homeostatic adjustments to HMG-CoA reductase inhibition increase clearance of LDL-C from plasma and decrease hepatic production of VLDL and LDL. In addition to blocking the synthesis of cholesterol, statins also interfere with the synthesis of lipid intermediates with important biologic effects. In the cholesterol synthetic

pathway, intermediate molecules of dimethylallyl pyrophosphate are metabolized by prenyltransferase into geranyl pyrophosphate and subsequently into farnesyl pyrophosphate. This step occurs before the formation of squalenes. These intermediates, geranylgeranyl and farnesyl, participate in protein prenylation, a mechanism by which a lipid moiety attaches covalently to a protein, thereby allowing anchoring into cell membranes and enhancing its biologic activity. Prenylated proteins important in cardiovascular signaling include the guanosine triphosphate-binding proteins Rho A, Rac, and Ras. Statins may increase HDL-C in part by preventing the geranylgeranylation of Rho A and phosphorylation of peroxisome proliferator-activated receptor- α (PPAR- α), a factor that regulates apo A-I transcription. Altered protein prenylation may also mediate some of the effects attributed to statins not related to a reduction in LDL-C levels.

Atherosclerosis involves inflammation (see Chapters 41 and 42). Statins decrease C-reactive protein (CRP), augment the collagen content of atherosclerotic plaque, alter endothelial function, and decrease the inflammatory component of plaque. The clinical importance of these possible LDL-independent actions and differences in efficacy between statins for a given percent reduction in LDL-C remain speculative.

Statin Pharmacology

The currently available drugs are fluvastatin (Lescol), 20 to 80 mg/day; lovastatin (Mevacor), 20 to 80 mg/day; pravastatin (Pravachol), 20 to 40 mg/day; simvastatin (Zocor), 10 to 40 mg/day (the 80-mg dose may increase risk for rhabdomyolysis, especially within the first year of treatment); atorvastatin (Lipitor), 10 to 80 mg/day; and rosuvastatin (Crestor), 5 to 40 mg/day. Pitavastatin (Livalo) 2 to 4 mg/day, is available in some countries. Concomitant drugs that interfere with the metabolism of statins by inhibiting the cytochrome P-450 3A4 and 2C9 systems can increase plasma concentrations of statins. Such agents include antibiotics, antifungal medications, certain antiviral drugs, grapefruit juice, cyclosporine, amiodarone, and several others. The major side effects of statins have been attributed to muscle symptoms ranging from diffuse myalgias (normal creatinine kinase [CK] levels), seen in up to 10% of statin users, to myositis, defined as diffuse muscle pain with evidence of muscle inflammation and elevated CK levels. Increased CK levels are identified in a minority of statin users, and a causal link must be established by rechallenge. In many cases of statin-associated myositis, a neuromuscular disease is identified (inclusion myositis and myopathies of genetic origin and spinal cord compression). Rarely, rhabdomyolysis can be associated with statin use. This life-threatening situation is often associated with predisposing factors (advanced age, frailty, renal failure, shock, concomitant use of antifungal agents, antibiotics, the fibric acid derivative gemfibrozil, and hypothyroidism).²⁷

Statins are generally well tolerated; side effects include reversible elevation of transaminases and myositis, which necessitates discontinuation of use of the drug in fewer than 1% of patients. After initiation of statin therapy, the response should be checked within the first 3 months, along with transaminase and CK levels. Thereafter, clinical judgment should dictate the interval between follow-up visits. Although frequent visits are probably not useful for the detection of serious side effects, they serve to encourage compliance and adherence to diet and lifestyle changes.

Clinical Trials with Statins

Twenty-seven trials with more than 1000 subjects randomly assigned to a statin versus a placebo (or a statin comparator) have reported effects of statins on cardiovascular outcomes (reviewed in previous versions of this chapter and elsewhere^{2,28}). Investigating a strategy of "lower LDL is better," five trials compared moderate with more robust LDL-C reduction by using maximum doses of atorvastatin or simvastatin. The A to Z (Aggrastat to Zocor), PROVE-IT (Pravastatin or Atorvastatin Evaluation and Infection Therapy), TNT (Treating to New Targets), IDEAL (Incremental Decrease in End points through Aggressive Lipid lowering), and SEARCH (Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine) trials showed

that more intensive reduction of LDL-C in patients at high or very high risk for recurrent CAD events further reduced risk in comparison to more modest LDL-C lowering. A recent meta-analysis of statin trials has compiled these data (Fig. 45-6).²⁸ Taken together, these data support prompt initiation of highly effective statin therapy in patients with acute coronary syndromes. Starting statin administration in the hospital may also improve compliance on discharge.

Before the availability of highly effective statins, a number of small angiographic trials demonstrated slowed progression of stenosis with dietary or various drug therapies to manage elevated total cholesterol and LDL-C. The advent of later-generation statins permitted more aggressive reduction of LDL-C. The REVERSAL (Reversal of Atherosclerosis with Lipitor) trial used intravascular ultrasonography (IVUS) to examine the effect of different degrees of lipid lowering on plaque volume. Over an 18-month period, patients treated with pravastatin (40 mg/day) had a 25% drop in LDL-C, and those randomly assigned to atorvastatin (80 mg/day) had a 46% decrease to an average LDL-C level of 79 mg/dL (2.6 mmol/L). The more aggressive lipid-lowering regimen reduced lesion volume. The primary endpoint was a reduction in total atheroma volume, which increased by 0.4% with pravastatin but decreased by 2.7% ($P=0.02$) with atorvastatin. The ASTEROID study evaluated whether 24 months of treatment with rosuvastatin, 40 mg, resulted in regression of coronary atherosclerosis as measured by IVUS in 507 patients. During treatment with rosuvastatin, 40 mg, LDL-C decreased from 130 mg/dL (3.4 mmol/L) to 61 mg/dL (1.6 mmol/L); HDL-C increased by 14.7%. A total of 349 patients underwent follow-up IVUS after 2 years. Several efficacy parameters were used: the median change in percent atheroma volume decreased by 0.79%, and the median change in the most diseased subsegment decreased by 5.6% (both $P < 0.001$). No control or comparator group was used. ASTEROID showed that rosuvastatin at a dose of 40 mg promotes regression of coronary atherosclerosis. The SATURN study compared the effects of rosuvastatin, 40 mg, with those of atorvastatin, 80 mg, on coronary lesions by IVUS. Both drugs proved equivalent in their ability to decrease lesion progression.²⁹

Use of Statins in Particular Populations

Diabetic Subjects

Patients with diabetes should receive a statin. Multiple observational studies have documented a markedly increased risk for coronary heart disease (CHD) in adult diabetics over the long term. Preventive strategies with aspirin, angiotensin convertase inhibitors, tight glyce-mic control, and statins have all shown benefit. Data from the CTT (Cholesterol Treatment Trialists) meta-analysis of statin trials in subjects with diabetes showed a 21% reduction in CVD events and a 9% all-cause mortality benefit in favor of statins.³⁰ Current data demonstrate that the benefits of statin therapy by far outweigh the risk for development of diabetes.²⁸

Older Patients

Elderly patients represent a special challenge; age accounts for most of the attributable cardiovascular risk in patients older than 75 or 80 years, and the predictive value of elevated cholesterol decreases with increasing age. A recent meta-analysis of statin trials using data on patients older than 75 years showed a 22% relative reduction in all-cause mortality. This analysis provides no reasons to withdraw statins from older patients if clinically indicated. Physicians must nevertheless exercise caution in implementing preventive strategies in older patients already taking multiple medications. Of concern, age was the major determinant of cardiovascular risk in the Framingham Heart study. Clinical judgment must be applied before considering statin use in an otherwise healthy elderly subject.

Women

Controversy arose on the basis of selective analysis of data showing a lack of benefit of statins in women, especially in the primary prevention setting. Most studies were not statistically powered to show an effect in women. A meta-analysis of statin studies involving women showed a statistically significant reduction in the primary endpoint

FIGURE 45-6 Meta-analysis of clinical trials of statin therapy: proportional reduction in nonfatal myocardial infarction or coronary heart disease death versus absolute LDL-C reduction. The effects on major vascular events are shown for each of the 26 studies included in the meta-analysis. In the **left panel**, the unweighted rate ratios (RR) for each trial are plotted along with 99% CI. In the **right panel**, RRs are weighted per 1.0 mmol/L LDL-C difference at 1 year. Subtotals and totals with 95% CIs are shown by open diamonds. (From Baigent C, Blackwell L, Emberson J, et al: Efficacy and safety of more intensive lowering of LDL cholesterol: A meta-analysis of data from 170,000 participants in 26 randomised trials. *Lancet* 376:1670, 2010.)

of acute myocardial infarction, stroke, CVD-related death, arterial revascularization, and hospitalization for unstable angina in favor of statins. The available outcomes data do not support the contention that statins do not confer cardiovascular protection for women.^{31,32}

Nonwhites

The INTERHEART study has shown the universality of cardiovascular risk factors in a study of almost 15,000 patients with acute myocardial infarction versus healthy controls.³³ Even though most studies under-represent the number of nonwhite and various ethnic groups, current data provide no reason to think that lipid-lowering therapy will not reduce cardiovascular risk in various ethnic groups. The MEGA study included Japanese men and women. JUPITER included more than 4400 black or Hispanic individuals and showed no heterogeneity in response to statin therapy in comparison to white individuals.

Advanced Heart Failure

Recent studies have addressed the issue of statin treatment of patients with advanced heart failure (left ventricular ejection fraction <30%).

The CORONA (Controlled Rosuvastatin in Multinational Trial in Heart Failure) and GISSI heart failure trials examined the effect of rosuvastatin on cardiovascular outcomes in subjects with reduced systolic function. These studies suggest that statin therapy does not reduce CVD-related morbidity or mortality in patients with advanced heart failure of ischemic or nonischemic cause.

Renal Failure

Several trials have examined the use of statins in patients with renal failure and in patients undergoing hemodialysis for end-stage renal disease. SHARP (Study of Heart and Renal Protection) examined the effects of simvastatin alone or combined with ezetimibe in patients with renal failure (N = 9270, 3023 of whom were being treated with dialysis). After a median follow-up of approximately 5 years, a 17% proportional reduction occurred in major atherosclerotic events (11.3% in the simvastatin plus ezetimibe group versus 13.4% in the placebo group; relative risk [RR], 0.83; 95% confidence interval [CI], 0.74 to 0.94; $P = 0.0021$).³⁴ In a further meta-analysis of trials including patients with renal failure, statins reduced all-cause mortality (RR,

0.81; 95% CI, 0.74 to 0.88), cardiovascular mortality (RR, 0.78; CI, 0.68 to 0.89), and cardiovascular events (RR, 0.76; CI, 0.73 to 0.80) in persons not receiving dialysis. Moderate- to high-quality evidence indicated that statins had little or no effect on all-cause mortality (RR, 0.96; CI, 0.88 to 1.04), cardiovascular mortality (RR, 0.94; CI, 0.82 to 1.07), or cardiovascular events (RR, 0.9; CI, 0.87 to 1.03) in persons undergoing dialysis.³⁵ Patients with chronic kidney disease have cardiovascular risk at least equivalent to that in patients with diabetes, thus emphasizing the need for prompt recognition and aggressive therapy.³⁶ Whether patients with end-stage renal failure undergoing dialysis benefit from LDL-C-lowering therapies, however, is unclear.

Taken together, the heart failure trials and the renal failure trials suggest that lipid management strategies in patients with end-stage renal disease produce limited improvement in outcomes. Clinical judgment must carefully weigh the benefits of such preventive measures in these patients.

Risks Associated with Low Low-Density Lipoprotein Cholesterol

Taken together with the cumulative evidence from large-scale clinical outcomes data, reaching a low total cholesterol and LDL-C state decreases cardiovascular risk. Some have expressed concern that low LDL-C could impair health. Several lines of evidence argue against this concern. (1) Most animals have little or no LDL-C and produce LDL particles only when dietary consumption of cholesterol and saturated fats increases. (2) Because of its importance in cellular functions, most (if not all) cell types have the cellular machinery to make cholesterol endogenously. (3) The HDL transport system, via the SR-B1 receptor, appears to be able to deliver cholesterol from hepatic sources to organs. (4) LDL deficiency states in humans, hypobetalipoproteinemia caused by mutations within the *APOB* gene, and loss-of function mutations within the *PCSK9* gene are associated with normal health and a marked reduction in life-long cardiovascular events.¹⁸ The CTT meta-analysis of more than 90,000 patients treated with statins has not shown an increase in cancers,^{2,37} and the JUPITER trial did not show increases in cancers, renal or hepatic diseases, or hemorrhagic strokes despite one fourth of the patients having reached an LDL-C concentration lower than 44 mg/dL (1.2 mmol/L) for up to 5 years. The CTT meta-analysis of statin trials did not identify any signal of harm in patients treated with statins.

Targeting Statin Treatment

Because the interaction of multiple coronary risk factors has received greater clinical importance, recommendations for clinical practice have increasingly embraced the concept of global risk management (see Chapter 42). Global risk algorithms consider not only total cholesterol but also HDL-C, smoking, age, hypertension, and sex (see Chapter 42). Tools are available online to determine the 10-year risk for the development of CVD. The Framingham Risk Score³⁸ forms the basis for risk determination in North America and Canada.³⁹ The European SCORE (Systemic COronary Risk Evaluation) determines the risk for cardiovascular death and is used in many European countries.⁴⁰ The Reynolds risk score includes family history and inflammatory status.⁴¹

Because global risk assessment shifts emphasis away from abnormal lipids alone to the patient's overall risk profile, it raises an important issue for the future of lipid management. That is, should the decision to initiate lipid modification for reduction of cardiovascular risk be based on high risk or high cholesterol? Recent trials have evaluated this question.

Large trials of statin therapy involving the secondary prevention of CAD and acute coronary syndromes, high-risk primary prevention, and selective primary prevention have been reviewed recently. There is some overlap between studies in terms of entry criteria, especially as it pertains to secondary prevention and high-risk prevention. Some studies include diabetic subjects and others use diabetes as an entry criterion. The cumulative data indicate that (1) statin therapy lowers the relative risk for major cardiovascular events in relation to the absolute magnitude of LDL-C reduction; (2) statins are well tolerated

and the benefits in most patients far outweigh the potential risks; (3) the absolute benefits correlate with baseline risk—from a purely economic point of view, the higher the cardiovascular risk, the greater the benefit; and paradoxically, (4) the large-scale impact of LDL-C reduction on a lower-risk population is likely to confer societal benefits in terms of reduction of CVD, albeit at a high monetary cost.^{2,37}

Statins and Risk for Diabetes

The use of statins is associated with a small but significant increase in diabetes.⁴² Further analysis of the clinical study data shows that statins hasten the diagnosis almost exclusively in subjects with pre-existing risk factors for the development of diabetes, such as baseline elevation of plasma glucose levels (Fig. 45-7).⁴³ Based on the available clinical study data, the overwhelming benefits of statin use in subjects at high risk for or in the secondary prevention of CVD exceeds the small risk for development of diabetes (Fig. 45-8).²⁸ Nevertheless, statin therapy should accompany a diet and exercise program aimed at achieving a healthy diet and ideal body weight.

Cholesterol Absorption Inhibitors

The development of selective inhibitors of intestinal sterol absorption has added to the treatment of lipoprotein disorders. Ezetimibe is the

FIGURE 45-7 Statin treatment does not provoke diabetes in those without major risk factors. The cumulative incidence of diabetes is shown in participants with (top) and without (bottom) major risk factors for diabetes (metabolic syndrome, impaired fasting glucose, body mass index of 30 kg/m² or higher, or HbA1c greater than 6% at entry.) Those with such risk factors crossed the threshold for diagnosis of diabetes only by 5.4 weeks. (From Ridker PM, Pradhan A, MacFadyen JG, et al: Cardiovascular benefits and diabetes risks of statin therapy in primary prevention: An analysis from the JUPITER trial. *Lancet* 380:565, 2012.)

FIGURE 45-8 Statin treatment reduces cardiovascular events in those with or without risk factors for the development of diabetes. Hazard ratios and 95% CIs are presented for specific vascular events, total mortality, and diabetes in subgroup analyses in participants with and without major risk factors for diabetes (metabolic syndrome, impaired fasting glucose, body mass index [BMI] of 30 kg/m² or higher, or HbA1c greater than 6% at entry. VTE = venous thromboembolism.) (From Ridker PM, Pradhan A, MacFadyen JG, et al: Cardiovascular benefits and diabetes risks of statin therapy in primary prevention: An analysis from the JUPITER trial. *Lancet* 380:565, 2012.)

first such compound. Ezetimibe limits selective uptake of cholesterol and other sterols by intestinal epithelial cells by interfering with NPC1L1. This agent has seen use in patients with LDL-C levels above target while receiving the maximally tolerated statin dose. Ezetimibe lowers LDL-C by about 18% and adds to the effect of statins. Because ezetimibe also prevents the intestinal absorption of sitosterol, it might be the drug of choice in cases of sitosterolemia. The current dose of ezetimibe is 10 mg/day. Studies evaluating the effects of ezetimibe on cardiovascular endpoints are ongoing.³⁰ The recently published result of SHARP suggests that ezetimibe combined with simvastatin therapy can reduce cardiovascular events in subjects with advanced renal impairment.³⁴ This study, however, did not determine whether ezetimibe added to the effect of the statin, because it lacked an arm to determine outcomes with statin alone.

Fibric Acid Derivatives (Fibrates)

Two derivatives of fibric acid are currently available in the United States. Gemfibrozil (Lopid) is used at a dose of 600 mg twice a day and is indicated for hypertriglyceridemia and in the secondary prevention of CVD in patients with low HDL-C levels. These latter recommendations are based on VA-HIT (Veterans Administration HDL Intervention Trial). The dose of fenofibrate (TriCor, Trilipix, Lipidil Micro, Lipidil EZ) is 200 mg/day, and a new formulation is available to vary the dose from 40 mg (especially in patients with renal failure) to 267 mg/day. In other countries, ciprofibrate (Lypanthyl, Lipanor), clofibrate (Atromid), and bezafibrate (Bezalip) are available.

The mechanism of action of fibrates involves interaction with the nuclear transcription factor PPAR- α , which regulates transcription of the LPL, apo C-II, and apo A-I genes. Side effects of fibrates include cutaneous manifestations, gastrointestinal effects (abdominal discomfort, increased bile lithogenicity), erectile dysfunction, elevated transaminase levels, interaction with oral anticoagulants, and elevated plasma homocysteine, especially with fenofibrate and, to a lesser extent, with bezafibrate. Because fibrates increase LPL activity, LDL-C levels may rise in patients with hypertriglyceridemia treated with this class of medications. Fibrates, especially gemfibrozil,

can inhibit the glucuronidation of statins and thus retard their elimination. For this reason, gemfibrozil combined with statins may increase the risk for myotoxicity; therefore such a combination is contraindicated. The clinical usefulness of fibrates is not well established, particularly in view of failure of the FIELD and ACCORD trials to achieve their primary endpoints. Subgroup analyses suggest a benefit of some fibrates in individuals with baseline high triglyceride levels, but no large endpoint study has tested this conjecture rigorously. Some advocate their use in very high-risk subjects such as diabetic patients with CVD and patients with renal failure.⁴⁴

Older fibrate trials such as the Helsinki Heart Study, BIP, and VA-HIT have little relevance to current practice because they did not use statins, which would be considered standard of care today for most patients eligible for fibrate therapy. Gemfibrozil, used in such older studies, has little relevance to current therapy because of a drug-drug interaction that renders concomitant administration with statins contraindicated. The FIELD trial examined the effect of fenofibrate, 200 mg/day, on the development of CHD in 9795 patients 50 to 75 years of age with diabetes for 5 years. The primary composite endpoint of CHD-related death or nonfatal myocardial infarction did not differ significantly between the fenofibrate and placebo groups (5.2% versus 5.8%, $P = 0.16$). A greater “drop in” of statin use in the placebo group (17%) versus the fenofibrate group (8%) may have led to underestimation of a potential benefit of the fibrate. The ACCORD trial examined the effect of tight diabetes control (HbA1c <6%), blood pressure control, and the use of fenofibrate in diabetes subjects treated on a background of mandated statin therapy. The fenofibrate arm of the trial did not meet its primary endpoint. Even though the overall effect of fibrates is neutral on cardiovascular mortality, subgroup analysis suggests that fibrates might be indicated in high-risk subjects with residual cardiovascular risk characterized by elevated triglyceride levels, reduced HDL-C, and elevated non-HDL-C who are receiving statin therapy.⁴⁵

Another consideration with the use of fibrates is the theoretical prevention of pancreatitis in patients with severe hypertriglyceridemia (>11 mmol/L; 1000 mg/dL). Yet fibrates have little usefulness in LPL-deficient patients with hyperchylomicronemia. Lifestyle changes, including a marked reduction in fats, especially saturated fats; tight

control of glycemia in diabetics; avoidance of alcohol; frequent small meals during the acute phase of a severe episode of hypertriglyceridemia; fish oil consumption; and avoidance of estrogens in women remain the fundamentals of prevention of pancreatitis in hypertriglyceridemic individuals.

Nicotinic Acid (Niacin)

Niacin increases HDL-C and lowers triglyceride levels but has more modest effects on LDL levels. Niacin requires doses in the range of 2000 to 3000 mg/day in three separate doses to maximize effects on lipid levels. An escalating dose schedule to reach the full dose in 2 to 3 weeks rather than starting with the full dose can help manage the adverse effects of this agent. Slow-release forms of niacin, including Niaspan (1 to 2 g/day), decrease the side-effect profile of the drug. Daily aspirin intake can attenuate skin flushing, as does the prostaglandin D₂ receptor (DP1) antagonist laropiprant. Niacin decreases the hepatic secretion of VLDL and reduces FFA mobilization in the periphery. In the long-term follow-up of the Coronary Drug Project, which was conducted before the availability of statins, niacin decreased mortality at 15 years. Significant and common minor side effects, much less frequent serious adverse actions, and the development of statins hamper its use. Side effects of niacin include flushing, hyperuricemia, hyperglycemia, hepatotoxicity, acanthosis nigricans, and gastritis. Long-acting niacin has the advantage of a once- or twice-daily dosing schedule, but older preparations of slow-release niacin were potentially more hepatotoxic. Niacin effectively raises HDL-C levels and, in combination with a low-dose statin, can retard the angiographic progression of CAD and decrease the frequency of adverse cardiac events. The mechanism of action of niacin remains unsettled. The identification of cell surface receptors for nicotinic acid that belong to the G protein-coupled heptahelical superfamily (GPR109A) does not account for the lipid-lowering effects.⁴⁶ Recent clinical trials do not support the ability of niacin therapy to improve cardiovascular outcomes in patients receiving statins. AIM-HIGH (Atherothrombosis Intervention in Metabolic syndrome with low HDL/high triglycerides: Impact on Global Health outcomes) tested the hypothesis that patients with CAD optimally treated with a statin but with residual atherogenic dyslipidemia (low HDL-C and high triglycerides) would benefit from niacin, 2 g/day. The trial was abruptly stopped after 3 years because of a lack of beneficial effect on the primary outcome.⁴⁷ The large HPS2-THRIVE (Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events) study randomly assigned 25,673 people with CVD to a strategy of LDL-C reduction with simvastatin (with ezetimibe, if required, to reach target goals) alone or in combination with niacin, 2 g/day, or laropiprant to limit the cutaneous flushing.⁴⁸ The THRIVE investigators announced in December 2012 that this intervention did not produce clinically meaningful reductions in cardiovascular events. The results of AIM-HIGH and THRIVE cast doubt on niacin's ability to lower cardiovascular risk and present yet another challenge to the hypothesis that elevation of HDL can improve outcomes of individuals treated with statins.

Cholesteryl Ester Transfer Protein Inhibitors

Inhibition of CETP by pharmacologic agents mimics the genetic heterozygous CETP deficiency state (see Fig. 45-4, path ⑨). Of several agents tested in humans, torcetrapib proved toxic and increased mortality, an effect attributed to off-target effects. Dalcetrapib, another CETP inhibitor, had more modest effects on HDL-C and LDL-C, and investigations on its use were stopped because of lack of effect in clinical trials.⁴⁹ Two CETP inhibitors, anacetrapib and evacetrapib, are undergoing large, outcome-driven clinical trials. In the DEFINE (Determining the Efficacy and Tolerability of CETP Inhibition with Anacetrapib) study, HDL-C was increased by 138% and LDL-C reduced by almost 40%. There was no untoward effect on blood pressure or markers of mineralocorticoid and potassium homeostasis.⁵⁰ CETP inhibitors markedly increase larger, more buoyant HDL particles; these particles appear to promote cellular cholesterol efflux effi-

ciently. Results of these ongoing trials are expected by 2016 to 2017. Because of the significant LDL-C-lowering effects of the CETP inhibitor anacetrapib, it may prove difficult to determine whether any benefit that it produces is derived from raising HDL-C levels.

Fish Oils

Fish oils are rich in polyunsaturated fatty acids such as eicosapentaenoic acid or docosahexaenoic acid, with the first double on the omega-3 position. These fatty acids lower plasma triglyceride levels and have antithrombotic properties. Although used for the treatment of hypertriglyceridemia, they are reserved for patients with severe hypertriglyceridemia refractory to conventional therapy. Fish oils decrease VLDL synthesis and decrease VLDL apo B. The response to fish oils depends on the dose, with a daily intake of up to 10 g of eicosapentaenoic acid or docosahexaenoic acid being required for maximal reduction of plasma triglyceride levels. Fish oils may raise LDL levels. A prescription form of omega-3 fatty acids has become available in the United States for use in patients with extreme hypertriglyceridemia (>500 mg/L or 5.6 mmol/L). A diet containing polyunsaturated fats may be beneficial in terms of cardiovascular health.⁵¹ We lack robust and rigorous clinical trials to examine the effects of fish oil on myocardial infarction and stroke events.

Phytosterols

Phytosterols are derivatives of cholesterol from plants and trees. They interfere with the formation of micelles in the intestine and prevent intestinal absorption of cholesterol. They are available as "nutraceuticals" and are incorporated in soft margarines. Sterols may prove useful for the adjunctive management of lipoprotein disorders, and current guidelines include them as part of the therapeutic lifestyle change regimen.

Novel Agents

In severe hypercholesterolemia, especially autosomal dominant hypercholesterolemia, several approaches have been approved to reduce LDL-C. Inhibition of MTP with the small molecule mipomersen reduces LDL-C by approximately 50%.⁵² Another approach is to inhibit apo B mRNA with phosphorothioate-linked antisense oligonucleotides. Mipomersen is the first such compound approved for limited use in patients with homozygous FH. Reductions of 20% to 30% in LDL-C are seen with mipomersen.⁵³ Although safety concerns were raised with these compounds, the severity of homozygous FH was deemed to warrant novel therapeutic avenues. Inhibition of apo B synthesis and secretion is associated with accumulation of fat in the liver. Because of the small number of patients included in these trials, no outcome data are likely to become available.

A CLINICAL APPROACH TO THE TREATMENT OF LIPOPROTEIN DISORDERS

Patients with lipoprotein disorders should undergo comprehensive evaluation and management in the context of a global risk reduction program. Most patients with dyslipoproteinemias lack symptoms, except for those with severe hypertriglyceridemia, who can have acute pancreatitis, and those with familial lipoprotein disorders, who have cutaneous manifestations (xanthomas, xanthelasmas). Evaluation of patients with dyslipidemia should include seeking and treating secondary causes. Clinical evaluation should include a thorough history, including a complete family history, which may reveal clues to a genetic cause, as well as clues to a genetic susceptibility to CVD. The physician should seek and address other risk factors (cigarette smoking, obesity, diabetes, hypertension, lack of exercise) and institute a management plan to improve lifestyle, such as diet, physical activity, and alcohol intake. Such interventions should make use of nonphysician health professionals (e.g., those with training in diet and nutrition, physical therapy, and smoking cessation). The NCEP

TABLE 45-7 Laboratory Tests for the Diagnosis of Lipoprotein Disorders

LIPOID PROFILE	MAY HELP IN DIAGNOSIS	SPECIALIZED CENTERS	RESEARCH TOOLS
Cholesterol	Apo B	Lipoprotein separation by UTC	Molecular diagnosis
Triglycerides	Apo A-I	LDL particle size (NMR, PAGE)	
LDL-C*		HDL particle size (NMR, PAGE)	
HDL-C			
Non-HDL-C	Direct LDL-C measurement	Specific enzyme assays (LCAT, LPL)	Cell-based assays LDL receptor binding/uptake Cellular cholesterol efflux
	Lipoprotein(a)	Apo E levels	
	Apo E genotype/phenotype	Apolipoprotein separation by PAGE: Apo CI-I, C-III	
		Sterol analysis by gas chromatography	

*Calculated as LDL-C = Total cholesterol – [(Triglycerides/2.2) – HDL-C] (in mmol/L) (or triglycerides divided by 5 in mg/dL); valid for triglycerides lower than 4.5 mmol/L (<400 mg/dL). LDL-C can also be directly measured in plasma.
NMR = nuclear magnetic resonance; PAGE = polyacrylamide gel electrophoresis; UTC = ultracentrifugation.

Adult Treatment Panel III (ATP III) Therapeutic Lifestyle Change Program offers one such approach. Concomitant medication use in addition to lifestyle change will often be needed to achieve current guideline goals.

The physical examination should include a search for xanthomas (in extensor tendons, including the hand, elbow, knee, and Achilles tendons, as well as palmar xanthomas) and the presence of xanthelasma, corneal arcus, and corneal opacifications. Blood pressure, waist circumference, weight, and height should be recorded and signs of arterial compromise sought, and a complete cardiovascular examination must be performed. Evaluation of peripheral pulses and determination of the ankle-brachial index may reveal important clues to the presence of peripheral vascular disease.

The diagnosis of lipoprotein disorders depends on laboratory measurements (Table 45-7). The fasting lipid profile generally suffices for most lipoprotein disorders, and specialized laboratories can refine the diagnosis and provide expertise for extreme cases. Additional tests often involve considerable expense and may not increase the predictive value beyond that of the lipid profile, although they can help in refining the diagnosis. To assess baseline risk in individuals receiving lipid-lowering therapy, the medication should be stopped for 1 month before measuring a lipid profile unless clinical circumstances contraindicate such a treatment gap. Advanced lipid tests (see Table 45-7) seldom add to the clinical assessment specified here.

After diagnosis of a lipid disorder (based on at least two lipid profiles), measurement of TSH and glucose help in evaluating secondary causes. Measurement of HbA1c and the urinary albumin-creatinine ratio may provide additional information in diabetic and hypertensive subjects. Patients who will receive medications should undergo measurement of baseline liver function (alanine aminotransferase) and CK. Drug treatment of high-risk subjects (e.g., patients with an acute coronary syndrome or after myocardial infarction or coronary revascularization) should start immediately concomitantly with lifestyle changes.

Target Levels

The NCEP ATP III made recommendations for the treatment of hypercholesterolemia. Target levels depend on overall risk for cardiovascular death or nonfatal myocardial infarction. Patients with CAD or atherosclerosis of other vascular beds (carotids or peripheral vascular disease), adults with diabetes, and those with an estimated 10-year risk for the development of CAD of greater than 20% fall into a high-risk category and merit aggressive treatment, including medications along with lifestyle modifications, exercise, and diet to achieve a primary target of an LDL-C level lower than 2.6 mmol/L (100 mg/dL). In subjects with triglycerides greater than 200 mg/dL, ATP III presents a secondary target of a non-HDL-C level lower than 3.4 mmol/L (130 mg/dL). Many of these individuals have metabolic

syndrome. A stricter LDL-C target for patients with acute coronary syndromes to less than 80 mg/dL (1.8 mmol/L) derived support from clinical studies, such as the PROVE-IT and A to Z trials.

The American College of Cardiology/American Heart Association Task Force on Practice Guidelines has issued a report⁵⁴ recommending LDL-C lowering with high-dose statin in the secondary prevention of CHD. Target levels are no longer advised, although an approximately 50% reduction in LDL-C is expected. The report adheres strongly to evidence-based principles, and specifically targets four patient groups, including subjects with (1) clinical atherosclerotic cardiovascular disease (ASCVD); (2) LDL-C >190 mg/dL, often representing familial hypercholesterolemia; (3) diabetes, aged 40 to 75 years, with LDL-C 70 to 189 mg/dL and without clinical ASCVD; or (4) no ASCVD or diabetes, with LDL-C 70 to 189 mg/dL, and estimated 10-year ASCVD risk >7.5%, using a new cardiovascular risk engine. These guidelines have generated some controversy and have not been adopted in Europe and Canada.

Lifestyle Changes Treatment

Therapeutic options consist of lifestyle modifications, treatment of secondary causes, and if possible, diet and medications.

Diet

Individuals with dyslipoproteinemias should always adopt dietary therapy. High-risk subjects should have medications started concomitantly with a diet because in many cases, diet may not suffice to reach target levels. The diet should have three objectives. First, it should allow the patient to reach and maintain ideal body weight. Second, it should provide a well-balanced diet with fruits, vegetables, and whole grains, and third, it should be restricted in sodium, saturated fats, and refined carbohydrates. Dietary counseling should involve a professional dietitian. Frequently, the help of dietitians, weight loss programs, or diabetic outpatient centers can aid in achieving sustained weight loss. Currently, the ATP III and the American Heart Association recommend a diet in which protein intake represents 15% to 20% of calories, fats represent less than 35%, with only 7% from saturated fats, and the remaining calories being derived from carbohydrates. Cholesterol intake should be less than 300 mg/day.

Treatment of Combined Lipoprotein Disorders

Combined lipoprotein disorders, characterized by an increase in plasma total cholesterol and triglycerides, frequently occur in clinical practice and present difficult challenges. Patients with combined lipoprotein disorders have an increase in LDL-C and LDL particle number (as reflected by an increase in total or LDL apo B or

non-HDL-C), small dense LDL particles, increased VLDL-C and VLDL triglycerides, and a reduced HDL-C level. Patients with this pattern of combined dyslipidemia often have obesity and metabolic syndrome. Treatment should begin with lifestyle modifications consisting of a diet reduced in total calories and saturated fats, weight reduction, and increased physical activity. Drug treatment, when warranted, is aimed at correcting the predominant lipoprotein abnormality. Statins can reduce plasma triglyceride levels, particularly in individuals with high baseline levels. Fibrates reduce triglycerides and may change the composition of LDL to larger and less dense particles. The combination of a statin with a fibrate, however, has proved highly effective in correcting the laboratory abnormalities that characterize the combined dyslipoproteinemias, but as noted earlier, currently available clinical trials have not established that this approach prevents cardiovascular events. In view of the effects of gemfibrozil on glucuronidation of statins, we advise against use of gemfibrozil in combination with statins. Patients taking a fibrate plus a statin merit close medical follow-up for evidence of hepatotoxicity or myositis within the first 6 weeks of therapy and every 6 months thereafter. The combined use of a statin and ezetimibe for the treatment of severe hypercholesterolemia or to reach recommended target levels when monotherapy with a statin is either insufficient or causes unwanted side effects has good rationale, although unsubstantiated by clinical trials.

Other combinations, including fibric acid derivatives with bile acid-binding resins and niacin with bile acid-binding resins, have also proved useful in specific cases. The combination of fibrates or statins with niacin requires experience and care because of the risk for hepatotoxicity and myositis. The search for correctable causes (e.g., uncontrolled diabetes, obesity, hypothyroidism, and alcohol use) of combined dyslipidemia and the benefit of lifestyle modifications require reemphasis. Often, the help of dietitians, weight loss programs, or diabetic outpatient centers adds considerably to management.

Extracorporeal Filtration of Low-Density Lipoprotein

Patients with severe hypercholesterolemia, especially those with homozygous FH or severe heterozygous FH, may warrant treatment by extracorporeal elimination of LDL. These techniques use selective filtration, adsorption, or precipitation of LDL (or apo B-containing particles) after plasma separation. Specialized centers have LDL-pheresis available. This approach can dramatically reduce the risk for development of CVD and improve survival.

FUTURE PERSPECTIVES

Inhibitors of PCSK9 by humanized monoclonal antibodies (or by antisense or small inhibitory RNA) are undergoing extensive clinical trials. The results of phase II trials of SAR236553/REGN727 (Sanofi-Regeneron) and AMG145 (Amgen) show 60% to 70% reductions in LDL-C with twice-weekly or monthly subcutaneous injections of PCSK9 monoclonal antibody.^{19,55} Large phase III cardiovascular outcome trials are under way in selected patient populations and in those at high risk for CVD.

The development of novel pharmaceutical agents for the treatment of lipoprotein disorders will probably continue because CVD secondary to atherosclerosis represents the largest burden of disease in most countries for the near future. Novel therapies, especially inhibitors of PCSK9, show considerable promise for the treatment of severe hypercholesterolemia. These new agents will offer personalized medicine based on genotype and phenotype. Better targeting of high-risk individuals will allow optimization of expensive therapies. The finding that subjects who were previously identified as being at relatively low risk for CAD on the basis of their LDL-C levels but who have an elevated CRP level derive benefit from a statin in the primary prevention of CAD may radically alter the concept of cardiovascular risk stratification.

Novel therapies to raise HDL-C have received some support in a proof-of-concept clinical trial in which patients with an acute coronary syndrome were given weekly injections of apo A-I_{Milano}—reconstituted proteoliposomes. These reconstituted HDL particles differ

markedly from nascent HDL particles. Even though a reduction in atheroma volume was found, widespread application of such techniques remains confined to the experimental setting. Other therapeutic modalities for the treatment of atherosclerosis involving modulation of lipoprotein metabolism include the development of new inhibitors of CETP to increase HDL-C. Two new CETP inhibitors, anacetrapib and evacetrapi, are undergoing clinical trials. Pharmacologic modulation of HDL-C levels, including modulation with niacin, has not led to results proportional to those achieved for LDL-C. Potential modulators of HDL-C levels include SR-B1, the ABCA1 and ABCG1 pathways, apo A-I and its homologues, and mimetics.

Gene Therapy

Severe, homozygous, monogenic disorders may eventually be treated by gene therapy. The initial trials of gene therapy in patients with homozygous FH have not led to a major improvement and have largely been abandoned but the life-long burden of these rare disorders and the potential for cure make this approach very appealing. Other diseases, such as abetalipoproteinemia, LPL deficiency,⁵⁶ Niemann-Pick type C disease, sitosterolemia, and Tangier disease, may become targets for gene therapy. If the approach to correcting these disorders is successful, the more widespread application of gene-based therapies for the purpose of reducing potential cardiovascular risk will become a daunting medical, social, and ethical problem.

Societal Changes

It is extremely unlikely that atherosclerosis will be prevented and cured by drugs. Societal changes aimed at preserving the benefits of hygiene and public health measures and infrastructure—brought by the 19th century—will be maintained because they have greatly reduced human suffering and pestilence as a cause of death. Public health measures to reduce cigarette smoking have already shown an impact on rates of myocardial infarction when applied. As humanity continues to accommodate more than half the population in cities, organization of neighborhoods into local networks allowing energy expenditure (rather than conservation via easy access to motorized transportation) will become necessary, especially in affluent countries. Personal changes with respect to food consumption and caloric intake will remain a major challenge. Indeed, the changes in diet and physical activity that have occurred in the past 50 years (now spreading globally) probably contributed to the epidemic of obesity and the increased prevalence of lipoprotein disorders, hypertension, and diabetes, with consequent CVDs.

Together with smoking and physical activity, dietary habits constitute the foundation for causation, prevention, and treatment of most cardiometabolic diseases, including coronary heart disease (CHD), stroke, type 2 diabetes mellitus (DM), sudden cardiac death, atrial fibrillation, heart failure, and vascular cognitive decline. In 2010, 8 of the top 25 modifiable causes of all global morbidity and mortality, expressed as disability-adjusted life-years, were dietary, including insufficient intake of fruits, nuts, whole grains, vegetables, seafood, omega-3 fatty acids, and dietary fiber and excess intake of salt and processed meats.¹ The global burden from suboptimal dietary habits has increased substantially in recent decades because of rapid social, cultural, and environmental transitions transmitted primarily through changes in diet and other lifestyle-related behavior.¹ Familiarity with evidence of the beneficial and harmful effects of specific dietary factors is essential to prioritize interventions for individual patients and for populations and to reduce the tremendous disease burden caused by suboptimal diets.

The science of nutrition and chronic diseases has progressed rapidly in recent years. Whereas previous dietary guidance was derived largely from ecologic studies, short-term experiments, and animal studies, nutritional science has been transformed by more robust evidence from prospective cohorts and randomized trials of cardiovascular disease (CVD) endpoints and well-conducted metabolic trials of multiple risk markers and pathways. One key lesson learned is that dietary habits influence virtually all established and emerging risk factors, including blood pressure (BP), glucose-insulin homeostasis, lipoprotein concentration and composition, weight gain, inflammation, endothelial function, and cardiac function and arrhythmia. Consequently, the effects of a dietary factor on disease risk should never be inferred only from its effects on any single risk factor, such as blood cholesterol concentrations.² For several diet-disease relationships, robust concordant evidence is now available across many different research paradigms. A second key lesson is the importance of foods and overall dietary patterns, rather than single isolated nutrients, for treating and preventing cardiometabolic diseases. This chapter reviews dietary factors with the strongest evidence of cardiometabolic effects and highlights key knowledge gaps. Because translation of knowledge into action is essential, this chapter also reviews effective individual- and population-based strategies for changes in behavior.

FOODS

In the early and mid-20th century, nutritional science and dietary guidelines concentrated mainly on diseases caused by deficiency of

nutrients, which resulted in corresponding emphasis being placed on isolated single nutrients to prevent disease.³ When nutritional focus subsequently shifted to chronic diseases, this emphasis on single nutrients nonetheless lingered. With few exceptions, however, single nutrients in isolation have little effect on cardiometabolic diseases. More relevant is the influence of foods and dietary *patterns*, a complex matrix of fatty acids, proteins, carbohydrate quality, micronutrients, and phytochemicals that together modify cardiometabolic risk.^{3,4} A focus on foods rather than single nutrients also facilitates dietary guidance and change in behavior.

Fruits and Vegetables

Higher fruit and vegetable intake is consistently associated with a lower incidence of CHD and stroke (**Fig. 46-1**).⁵ Risk for DM involves similar, though not statistically significant trends, perhaps because of stronger associations of certain subtypes such as green leafy vegetables.⁶ In controlled trials lasting up to 2 years, diets with an emphasis on consuming fruits and vegetables substantially improve multiple cardiometabolic risk factors, including BP, lipid levels, insulin resistance, inflammation, adiposity, and endothelial function.⁷ In trials, the benefits of fruit and vegetable intake cannot be reproduced with equivalent amounts of potassium, magnesium, and fiber supplements⁸ and are largely independent of the macronutrient (fat, protein, or carbohydrate) content of the diet.⁹ This observation suggests that the benefits derive from a more complex set of micronutrients, phytochemicals, and fiber in fruits and vegetables, as well as from the replacement of less healthful foods. Together, these studies provide convincing evidence that fruit and vegetable consumption each lowers risk for CVD; notably, fruits and vegetables have similar overall effect sizes. The benefits of specific subtypes of fruits and vegetables, as well as 100% juice, require further study.

Whole Grains, Refined Grains, Starches, and Sweets

Improved understanding of how different carbohydrate-rich foods, which comprise about half of all calories in most diets, influence cardiometabolic risk represents a major advance in nutritional science. Although carbohydrates have traditionally been classified as simple (e.g., sugars such as glucose, fructose, galactose, sucrose, lactose, and lactulose) or complex (e.g., starches in grains and potatoes such as glycogen, cellulose, and hemicellulose), this distinction has little cardiometabolic relevance; simple sugars and refined carbohydrates or starches are each rapidly digested and absorbed after ingestion. Other characteristics more accurately define carbohydrate

FIGURE 46-1 Meta-analyses of foods and incidence of coronary heart disease, stroke, and diabetes. E = energy; PC = prospective cohort; RCT = randomized controlled trial; SFA = saturated fatty acid; — = not reported.

Type	Processing and Structure	Examples
Intact whole grains	Whole grain with the bran, germ, and endosperm from the natural cereal intact	Bulgur wheat, amaranth, wheat berries
Minimally processed whole grains	Some processing is performed to improve palatability or digestibility, yet the bran and germ remain partially intact	Stone-ground whole wheat bread, cracked wheat, steel-cut oats, brown rice
Milled whole grains	The whole grain, including bran, germ, and endosperm, is milled to fine flour	Most commercially available whole grain breads, whole grain breakfast cereals, whole grain pasta
Refined grains*	The bran and germ are removed during processing, leaving the endosperm comprised largely of refined starch	White bread, white rice, most ready-to-eat breakfast cereals, instant oatmeal, regular pasta
Starchy vegetables*	Plants that have been bred or engineered to contain high levels of starch with relatively low dietary fiber and micronutrients	Potatoes, corn*
Refined sugars*	Natural and industrially produced monosaccharides, disaccharides, and oligosaccharides, including sucrose, glucose, fructose, high-fructose corn syrup, maltose, dextrose, and maltodextran	Candies, other sugars added to foods
Sweetened refined grains*	Refined grains with added refined sugars	Sweetened breakfast cereals, grain-based desserts (cakes, cookies, pies, doughnuts, sweet rolls, muffins)
Refined sugars in liquid form*	Natural and industrially produced monosaccharides and disaccharides in liquid form	Sugar-sweetened beverages, including sodas, iced teas, sports drinks, and fruit drinks

FIGURE 46-2 Carbohydrate quality. No simple taxonomy to define healthier carbohydrate-rich or whole grains foods has been accepted. Partly overlapping characteristics that influence cardiometabolic health include dietary fiber content, whole grain (bran, germ) content, glycemic response to ingestion, and food structure (solid, liquid). Carbohydrate quality, as characterized by one or more of these measures, influences several cardiometabolic pathways, including glucose-insulin homeostasis, atherogenic dyslipidemia, weight gain, endothelial and inflammatory responses, and possibly metabolic expenditure. Such effects may be especially relevant postprandially and in individuals predisposed to insulin resistance. Based on these characteristics, carbohydrate-rich foods can be classified from the healthiest (dark green, top of chart) to the most harmful (dark pink, bottom of chart). For instance, minimally processed whole grains may have greater benefit than milled whole grains because of intact food structure and a lower GI, whereas refined sugars in liquid form may have greater adverse effects than other refined carbohydrates because of additional unfavorable effects on satiety and weight gain. *Simple and complex refined carbohydrates induce similarly high glycemic responses following ingestion and, in amounts typically consumed in Western diets, induce de novo hepatic lipogenesis (i.e., converting carbohydrates to fat). When compared with glucose, fructose (representing about half of all sugars in high-fructose corn syrup or sucrose, i.e., cane or beet sugar) produces smaller blood glycemic responses but more strongly stimulates de novo lipogenesis, which based on limited animal experiments and human studies may induce hepatic steatosis and insulin resistance. The cardiometabolic effects of foods containing lower amounts of naturally occurring sugars, such as fructose in fruits, appear to be more similar to whole grains than refined grains or sugars are, probably related to the relatively low sugar content; intact food structure, which slows digestion; and the benefits of accompanying dietary fiber, antioxidants, minerals, and phytochemicals. Corn provides reasonable fiber and modestly lower glycemic responses than do many types of potatoes. Yams and sweet potatoes are not included here because of higher nutrient content and lower glycemic responses to ingestion.

quality, including dietary fiber content, whole grain content, glycemic index (GI) and glycemic load (GL), and food structure (liquid versus solid).⁷ Even though total carbohydrate intake is not strongly associated with CVD, these interrelated characteristics of carbohydrate-rich foods have important effects on cardiometabolic risk (**Fig. 46-2**). The effects of dietary fiber and GI/GL, each determined by overall dietary patterns, including intake of whole grains, refined grains, starches, sweets, fruits, vegetables, nuts, seeds, and legumes, are reviewed later (see **Carbohydrates**).

The content of whole grain also appears to be relevant. Whole grains include endosperm, bran, and germ; the latter are stripped away during processing to produce refined grains, in which only the starch-rich endosperm remains. Bran provides fiber, B vitamins, minerals, flavonoids, and tocopherols, whereas germ provides fatty acids, antioxidants, and phytochemicals. Whole grain intake is consistently associated with lower risk for CVD, DM, and weight gain (see **Fig. 46-1**).^{10,11} In trials, whole grain intake improves glucose-insulin homeostasis, low-density lipoprotein cholesterol (LDL-C), and possibly endothelial vasodilator function and inflammation.¹¹ As with fruits and vegetables, no single nutrient appears to account

for these benefits, which may arise from multiple synergistic effects.⁴ Food structure is also relevant: carbohydrate-rich foods in liquid form, such as sugar-sweetened beverages (SSBs), are associated with even greater weight gain than equivalent solid foods are,¹⁰ probably related to less satiation when consuming liquid carbohydrates.

In contrast to whole grains, refined grains (e.g., white bread, rice, most breakfast cereals), starches (e.g., potatoes), and sweets are associated with greater weight gain,¹⁰ are a major determinant of dietary GI and GL, and are associated with greater risk for CHD and DM (**Fig. 46-3**). These effects are probably due to both direct metabolic harm (e.g., on postprandial glucose-insulin, endothelial, and inflammatory responses) and displacement of healthier foods (e.g., whole grains, fruits, vegetables). Additionally, harm may be greatest in those predisposed to insulin resistance, such as persons with DM, lower physical activity, or greater adiposity. Based on their prevalence in most diets, reducing the intake of refined grains, starches, and sugars, with replacement by whole grains, fruits, vegetables, and other healthier foods, is a major dietary priority. Because several interrelated factors influence their effects on health (see **Fig. 46-2**), no single accepted criterion exists for identifying healthful carbohydrate-rich foods. Choosing grain foods with a ratio of total carbohydrate to dietary fiber (grams per serving) of less than 10:1 appears to identify the most healthful grain choices better than other recommended criteria do.¹²

Nuts, Seeds, and Beans

Nut consumption has been associated with a lower incidence of CHD and DM in prospective cohorts (see **Fig.**

46-1)^{5,13,14}; with lower LDL-C and some evidence of improved oxidative, inflammatory, and endothelial responses in observational studies and controlled trials¹⁵⁻¹⁷; and with less long-term weight gain and lower body mass index in observational and some interventional studies.^{10,18} Potentially bioactive constituents include unsaturated fats, vegetable protein, fiber, folate, minerals, tocopherols, and phenolic compounds. The effects of different types of nuts require further study, but the benefits in short-term trials, the magnitude and consistency of lower risk in observational studies, and the large predicted disease burden because of low population intake¹ support an emphasis on modest nut consumption for lowering cardiometabolic risk.

The cardiovascular effects of seeds and beans (legumes) are less well established. In a limited number of cohorts, legume intake was inversely associated with CHD, but with not diabetes or stroke.¹⁴ Meta-analyses of small trials of soy foods suggest modest improvement in blood cholesterol levels, especially in diabetic patients, and small to no effects on multiple other risk factors, including glycemic control, BP, inflammation, and body weight, though with heterogeneity and occasional positive findings in some post hoc patient subgroups.¹⁹⁻²³ Both seeds and legumes provide an overall package

FIGURE 46-3 Meta-analyses of dietary nutrients and incidence of coronary heart disease, stroke, and diabetes. PC = prospective cohort; RCT = randomized controlled trial; — = not reported.

of micronutrients, phytochemicals, and fiber that could reduce cardiometabolic risk; this hypothesis requires further evaluation in controlled interventions and long-term cohorts.

Fish

Numerous prospective cohorts have reported on fish intake and CVD (see Fig. 46-1). Modest fish consumption is consistently associated with less fatal CHD, but only small or no association with total CHD or nonfatal myocardial infarction (MI).^{24,25} Meta-analyses of randomized trials of fish oil supplementation are consistent with these findings and demonstrate reductions in CHD mortality but not in other subtypes of CVD.²⁶ The evidence suggests a nonlinear benefit: modest consumption (~2 servings per week) significantly reduces risk versus no consumption, whereas higher consumption does not have appreciable further effects.²⁵

In observational studies, fish consumption has been associated with less ischemic stroke, but fish oil supplements have not been found to influence stroke in post hoc analyses of CHD trials.^{26,27} A few observational studies have evaluated other CVD outcomes, such as atrial fibrillation and heart failure, with mixed findings.²⁴ Many studies have evaluated incident DM, which is not associated with either overall fish consumption or circulating omega-3 biomarkers, although inverse associations are seen in Asian populations.^{28,29}

The types of fish consumed and the preparation methods may influence omega-3 blood levels and effects on CVD, with the greatest benefit being derived from nonfried oily (dark meat) fish, which contain up to 10-fold more omega-3 fatty acids than other species do.²⁴ Fish contains omega-3 and other unsaturated fats, selenium, and vitamin D. Prevention of death in patients with CHD appears to be related mainly to the omega-3 content; the health effects of omega-3 fatty acids are reviewed later (see [Macronutrients](#)). Methylmercury in fish has no detectable influence on CVD events or incident hypertension.^{30,31}

Meat

Although ingesting lean meat lowers saturated fat and cholesterol, the effects of meat consumption on cardiometabolic risk appear to be more complex, with other factors (e.g., sodium, heme iron) potentially being more relevant. The evidence available suggests that processed meat (i.e., meat preserved with sodium or other preservatives, such as deli meats, sausage, and hot dogs) increases the risk for both CHD and DM whereas unprocessed red meat has small or no effects on CHD but increases the risk for DM, though to a lesser extent than processed meat does.³² These divergent associations are seen despite relatively similar average amounts of saturated fat and cholesterol in processed and unprocessed red meat.³³ Conversely, differences in sodium content (~400% higher in processed meat) appear to account for about two thirds of this difference in the observed incidence of CHD.³² These findings, together with other evidence of little to no overall effect of saturated fat consumption on CHD or diabetes (see [Macronutrients](#)), suggest that the constituents most relevant to cardiometabolic effects may include dietary cholesterol, heme iron, and nitrates with respect to risk for DM, and sodium and nitrates with respect to risk for CHD.³² This evidence implies that clinical and public health guidance for achieving cardiometabolic health should especially prioritize reduced ingestion of processed meats, as well as lowering the content of sodium and other preservatives. Thus, promotion of processed deli meat sandwiches (e.g., low-fat processed chicken, turkey, or bologna) as “healthy” alternatives on the basis of lower total fat and saturated fat is unjustified. The few studies reporting on meat intake and incident stroke observed relatively small positive associations,³⁴ which limits strong conclusions on this endpoint.

Dairy

Dairy foods constitute a major portion of many diets, yet their cardiometabolic effects remain remarkably understudied. In randomized

trials, milk or dairy intake has been found to reduce body fat and increase lean mass in the setting of energy-restricted diets and to have little effect on body weight or composition in ad libitum diets.^{35,36} Long-term prospective cohort studies support the latter findings and have not observed any relationship of whole-fat or reduced-fat/nonfat dairy with long-term weight gain, except for an inverse association of yogurt, which requires further study.¹⁰ Multicomponent dietary trials, including low-fat dairy products, have shown improvements in BP, lipid levels, insulin resistance, and endothelial function,⁷ but such designs cannot extricate the specific effects of dairy products. Long-term cohort studies have found dairy consumption to be associated with a modestly lower risk for CHD, stroke, and DM (see Fig. 46-1), as well as a lower risk for metabolic syndrome or its components.³⁷⁻⁴⁰

The relevant active constituents in dairy foods remain unclear. In short-term interventions, calcium and linoleic acid (LA) have produced small or no effects on risk factors for CVD. Some observational studies suggest that dairy fat or potentially bioactive dairy fatty acids may have benefit.⁴⁰⁻⁴² Fermentation (i.e., the presence of active bacterial cultures) may also be relevant given growing recognition of the importance of the gut microbiome for health.⁴³ Overall, the data support guidelines for modest dairy consumption (two to three servings per day), but the active ingredients have not been defined sufficiently by current evidence to allow strong recommendations on choosing between whole-fat or low-fat dairy or between subtypes (e.g., milk, cheese, yogurt) for reducing CVD, DM, or adiposity.

BEVERAGES

Sugar-Sweetened Beverages

Ecologic data, prospective cohorts, and randomized trials together provide convincing evidence that SSB intake increases adiposity. In the United States, calories from beverages increased from 11.8% to 21.0% of all calories consumed between 1965 and 2002—an increase of 222 kcal per person per day, largely because of SSBs (sodas, energy drinks, sweetened ice teas, fruit drinks).⁴⁴ The average American teenage boy and girl consume 18 and 14 8-oz servings, respectively, of SSBs weekly⁴⁵; most consumption by youth occurs at home.⁴⁶ Per serving, SSBs are more strongly associated with long-term weight gain than nearly any other dietary factor.¹⁰ Randomized trials have confirmed that reducing SSB intake decreases weight gain and fat accumulation.⁴⁷⁻⁴⁹ Calories in liquid form, versus solid foods, appear to be less satiating and increase the total calories consumed.⁵⁰ SSB intake is also associated with a significantly higher risk for DM and metabolic syndrome,⁵¹ probably related to both weight gain and the independent harm of a high GL.

Milk

See Dairy.

Coffee and Tea

Although coffee and tea are often considered in terms of caffeine, they each represent liquid extracts of plants (coffee beans, tea leaves) containing many other compounds. Frequent coffee intake (three to four or more cups per day) in particular is associated with lower insulin resistance and risk for DM (see Fig. 46-1), unrelated to its caffeine content.^{52,53} Most such data are observational, however. Acutely, caffeinated coffee worsens BP, insulin resistance, and glucose intolerance.^{54,55} Yet long-term coffee intake does not raise BP or insulin resistance, thus suggesting tachyphylaxis and/or other partly offsetting factors.^{52,56,57} In prospective observational studies, coffee intake was not associated with CHD and was weakly associated with stroke.^{58,59} In a limited number of studies, coffee intake has been associated with less incident heart failure.⁶⁰ Drinking unfiltered coffee raises LDL-C; intake of instant or paper-filtered coffee has little effect.⁵²

Intake of black tea is not significantly associated with CHD, whereas intake of green tea is associated with lower risk, but this is based on few studies (Fig. 46-1).⁶¹ Frequent tea drinking (three or more cups per day) is associated with a modestly lower risk for stroke and DM.^{53,62} In short-term trials, green tea was found to lower LDL-C⁶³ and minimally affect weight loss or maintenance⁶⁴; fewer data are available on BP or endothelial function.⁶⁵ In one 6-month trial, three cups per day of black tea modestly reduced mean ambulatory systolic (−2 mm Hg) and diastolic (−2.1 mm Hg) BP at 6 months in comparison to controls, who abstained from regular tea drinking.⁶⁶ Overall, observational evidence supports the benefits of frequent coffee intake on incident DM, but little effect on CHD or stroke, whereas more mixed observations suggest possible benefits of frequent tea intake on DM and stroke. Strong conclusions on the cardiometabolic effects of coffee or tea will require further investigation, including both physiologic and clinical endpoint trials.

Alcohol

Habitual heavy alcohol consumption causes up to a third of cases of nonischemic dilated cardiomyopathy in many nations.⁶⁷ The ventricular dysfunction is often irreversible, even when alcohol use is stopped; continued drinking is associated with high mortality (see also Chapter 68). Habitual alcohol intake, as well as acute binges, is associated with a higher risk for atrial fibrillation.⁶⁸⁻⁷⁰ Like other liquid calories (except milk), alcohol intake is also associated with higher long-term weight gain.¹⁰ Conversely, when compared with nondrinkers, regular moderate consumption—up to about 2 drinks per day for men and around 1 to 1.5 drinks per day for women—is associated with a lower incidence of CHD and DM, but not stroke.^{71,72} Such observational analyses, however, could overestimate the benefits because of nondrinkers comprising individuals who had quit or never used alcohol as a result of poor health.⁷³ Yet the magnitude and consistency of the lower risk observed across diverse populations, together with favorable effects on high-density lipoprotein cholesterol (HDL-C), insulin resistance, and fibrinogen in controlled trials,⁷⁴ provide strong evidence for at least some cardiometabolic benefit of moderate alcohol intake. The health effects are due to the alcohol content; different drinks (e.g., red or white wine, beer, spirits) have similar cardiometabolic effects. Conversely, the drinking pattern is important: greater benefit is seen with regular moderate drinking than with irregular or binge drinking.⁷⁵ Because of alcohol-related cancers, liver disease, cardiomyopathy, accidents, homicides, and suicides, alcohol use produces major net adverse population health effects.^{1,76} Thus, alcohol use should not be advised as a means of reducing risk for CVD; adults who already use alcohol should drink moderately.

MACRONUTRIENTS

Carbohydrates

Although total carbohydrate intake is not strongly associated with risk for CHD (see Fig. 46-3), the quality of carbohydrate-rich foods consumed does influence metabolic health. The effects of whole grains versus refined grains, starches, and sweets are discussed earlier in this chapter.

Dietary Fiber

Dietary fiber consists of nondigestible polysaccharides, naturally occurring resistant starches and oligosaccharides, and lignins in plants, including whole grains, fruits, vegetables, nuts, seeds, and legumes. Higher fiber intake reduces multiple risk factors, including serum triglycerides (TGs), LDL-C, blood glucose, and BP.⁷⁷ Few long-term trials have been performed; in the Diet and Reinfarction Trial among men with previous MI, advice to consume foods higher in cereal fiber had no significant effect on CHD endpoints, but follow-up was limited to 2 years. Dietary fiber intake is inversely associated with CHD¹³; however, several studies have observed heterogeneity in this relationship, depending on the fiber type (soluble, insoluble), source

(e.g., fruits, vegetables, cereals), or participant characteristics (e.g., sex, smoking status), thus raising questions about the consistency and magnitude of the effect of dietary fiber itself.⁷⁷ The lower risk observed with fiber-rich foods is probably at least partly due to other beneficial compounds in these foods and/or substitution effects (i.e., replacement of more processed, less healthful foods). Thus, consumption of fiber-rich foods in place of refined grains and processed foods, rather than focusing on dietary fiber per se, is a sensible strategy for lowering cardiometabolic risk.

Glycemic Response

The GI quantifies the total postprandial rise in blood glucose (area under the curve) following ingestion of a carbohydrate-rich food.⁷⁸ The postprandial rise is standardized to that of a standard carbohydrate (e.g., white bread), calculated as a proportion (percentage) of the standard response times 100. Thus, foods with a GI of 100 induce the same postprandial glycemia as white bread does; foods with a GI of 50 induce half. A principal determinant is the extent of processing: disruption of the natural grain structure exposes the endosperm to digestive enzymes and accelerates absorption. Even high-fiber, whole grain foods (e.g., instant oats, most whole grain breads) can have a relatively high GI because of extensive milling and processing in comparison to less processed counterparts (e.g., steel-cut oats, stone-ground bread) (see Fig. 46-1). Thus, the GI provides a measure of carbohydrate quality independent of fiber or whole grain content. More processed and starchy foods have a higher GI (e.g., white bagel, 99; white rice, 103; whole wheat bread, 106; Gatorade, 111; corn flakes, 115; instant oats, 114; baked potato, 123), whereas less processed foods have a lower GI (e.g., stone-ground bread, 85; steel-cut oats, 74; apples, 56; milk, 45; lentils, 41; mixed nuts, 34).⁷⁹

The GI compares a fixed amount of carbohydrate (50 g) in each food, but certain foods contain very different amounts of carbohydrate. To account for this, the GL is derived by multiplying the GI by the usual amount of carbohydrate in each food ($GL = GI \times g$ per serving of carbohydrate). This distinction is crucial for fruits, which have a low absolute carbohydrate content. For example, the GI of watermelon and white rice is similar (103 per 50 g carbohydrate), but the GL of watermelon is much lower (4 versus 29, respectively).⁷⁹ Postprandial glycemia correlates with insulin and related counter-regulatory responses,⁷⁸ thus making the GL a reasonable measure of the postprandial metabolic effects of carbohydrate-rich foods.

When compared with foods and diets with a higher GI/GL, those with a lower GI/GL improve blood glucose control, TGs, and LDL-C, as well as perhaps inflammation, endothelial function, and fibrinolysis.^{78,80-83} Acutely, meals with a lower GI increase satiety⁸⁴; in some but not all short-term trials, lower GI/GL diets improve weight loss,^{85,86} and in long-term observational studies, foods with a high GL are strongly linked to weight gain.¹⁰ Remarkably, the GL may influence not only caloric intake but also energy expenditure. In a controlled feeding trial, diets with a higher GL led to greater declines in resting and total metabolic expenditure than did diets with a lower GL after weight loss.⁸⁷ Consistent with these adverse effects, diets with a higher GL have been associated with incident CHD, stroke, and DM in prospective studies (see Fig. 46-3).⁸⁸⁻⁹⁰

Fats

Total Dietary Fat Versus Fat Quality

Early ecologic (cross-national) studies suggested that higher fat intake might increase cardiometabolic risk, but more robust evidence from prospective cohorts and randomized trials has convincingly established that the proportion of energy consumed from fat has negligible effects on CHD or DM (see Fig. 46-3).^{13,91,92} Similarly, the percentage of total fat in foods or diets has little influence on weight loss, weight gain, or overweight/obesity (see Energy Balance). Lowering total fat intake variably alters blood lipid levels, depending on the specific subtypes of fat in the diet.⁹³ When total fat is reduced, carbohydrate intake typically increases, which can induce adverse effects if the carbohydrates are more refined and of lower quality (see earlier). Some prospective studies suggest that low fat intake might

increase the risk for stroke,⁹³ potentially related to low dietary cholesterol and vascular fragility.

In contrast to the limited relevance of total fat, the quality of dietary fat—that is, the specific types of fat and fatty acids consumed—has major effects on health. Dietary fats are traditionally classified into broad categories based on the numbers (e.g., saturated, monounsaturated, polyunsaturated) and positions (e.g., omega-3 [n-3], omega-6 [n-6]) of double bonds (see also Chapter 45). These broad groupings can obscure differences in dietary sources and the biologic effects of individual fatty acids within each class, which may exert specific influences on gene transcription, cell membrane fluidity and receptor function, and lipid metabolites. This chapter follows the conventional categories but highlights the effects of individual lipids when sufficient data exist.

Saturated Fatty Acids

Meats, dairy products, and tropical oils (e.g., palm, coconut) are major sources of saturated fatty acids (SFAs). Based on ecologic comparisons, effects on LDL-C, and animal experiments, SFA intake increases risk for CHD. Yet the SFA story is not so simple.⁹³ For instance, lauric (12:0), myristic (14:0), and palmitic (16:0) acids raise LDL-C relative to carbohydrate, but stearic acid (18:0) does not. Furthermore, even though the 12-, 14-, and 16-carbon SFAs raise LDL-C, they also each lower TGs, raise HDL-C, and increase apolipoprotein A-I (apo A-I) levels. When consumed in place of monounsaturated fatty acids (MUFAs) or carbohydrates, SFAs also lower lipoprotein(a).⁹⁴ Given these complex, divergent lipoprotein changes, a more global lipid risk marker, such as the total/HDL-C ratio, may be most informative and also correlates best with findings from prospective cohorts and clinical trials of disease endpoints.⁹⁵ When compared with carbohydrate, the total/HDL-C ratio is not altered by 14:0 or 16:0 SFA, is nonsignificantly decreased by 18:0 SFA, and is significantly decreased by 12:0 SFA.⁹³ These changes would predict minimal overall effects of higher SFA intake on CHD.

Prospective cohorts and clinical trials support these findings. In one large trial targeting fat reduction, SFA intake was reduced from approximately 12.5% to 9% energy (E), largely replaced with carbohydrates, without effects on incident CHD (relative risk [RR], 0.98), stroke (RR, 1.02), or diabetes (RR, 0.96).^{91,92} Similarly, in prospective cohorts, people consuming the highest amounts of SFA have a similar incidence of CVD as those consuming the lowest amounts (see Fig. 46-3).^{13,96,97}

Together, the results of lipid biomarker trials, prospective cohorts of CVD endpoints, and large clinical trials suggest that overall SFA intake minimally affects risk. Yet this absence of overall effect obscures the heterogeneity of individual SFAs, depending on the comparison nutrient and possibly the food source and subtype of SFA. Most notably, multiple research approaches have demonstrated that replacing SFAs with polyunsaturated fatty acids (PUFAs) lowers the risk for CHD (see Fig. 46-3) (see Polyunsaturated Fatty Acids, later).⁹⁵ Conversely, isocaloric replacement of SFAs with carbohydrates—the common dietary practice—has little effect⁹⁵; indeed, replacing SFAs with carbohydrates that have a high GI is linked to higher risk for CHD.⁹⁸ These findings indicate that increasing PUFA intake (i.e., vegetable oils) in place of either SFAs or carbohydrates is an effective strategy for reducing CHD (see Polyunsaturated Fatty Acids, later). Replacing SFAs with MUFAs has uncertain effects on CVD (see Monounsaturated Fatty Acids, below). The effects of SFAs may also depend on the food source. SFAs from meat sources are associated with higher risk for CVD, whereas SFAs from dairy are associated with lower risk.⁴² The effects of vegetable sources of SFAs on CVD remain understudied. In addition to other ingredients, different foods contain varying proportions of individual SFAs (e.g., 16:0, 18:0); how these different SFAs influence clinical outcomes remains unclear.⁹³

In sum, the effects of SFAs are heterogeneous and depend on the comparison nutrient, and also perhaps the food source and subtype of SFA—thus highlighting the limitations of SFA content as a major metric for defining healthful foods or diets. Better evidence-based targets for dietary change are the foods themselves (Table 46-1) and overall diet patterns (see Dietary Patterns).^{3,7,99-101}

Monounsaturated Fatty Acids

Animal fats and vegetable oils (e.g., olive, canola) are major sources of MUFAs, largely oleic acid (18:1 n-9). Oleic acid favorably affects BP and cholesterol concentrations^{93,102} but has been associated with a trend toward greater CVD events in pooled cohort studies¹⁰³; no controlled trials have evaluated its effects on clinical CVD endpoints. In nonhuman primates, oleic acid favorably influences blood cholesterol concentrations yet increases atherosclerosis, potentially because of alterations in LDL-C composition, including enrichment of cholesteryl oleate.¹⁰⁴ Trials of dietary MUFAs and glucose-insulin homeostasis have shown mixed findings. The largest trials have suggested that consuming MUFAs in place of SFAs lowers glucose levels in individuals predisposed to insulin resistance.^{93,105} Yet several large observational studies have not found any relationship between MUFA intake and incident DM.¹⁰⁶ Taken together, the evidence for a cardio-metabolic benefit of oleic acid is not strong.

Conversely, observational studies and randomized trials of overall dietary patterns that included MUFAs from olive oil, as part of an overall Mediterranean-type diet, have demonstrated improved risk factors for CHD and reduced risk for CHD events.^{13,107-110} Olive oil contains other ingredients—for example, phenolic compounds such as oleocanthal—that possess anti-inflammatory properties.¹¹¹ These compounds, especially rich in extra-virgin olive oil, may have principal responsibility for the link between extra-virgin olive oil consumption and lower risk for CVD in traditional Mediterranean populations. However, potential dose-response relationships for phenolic compounds have not been established; indeed, their clinical benefits remain speculative. The overall evidence does not strongly support increasing intake of MUFAs per se as a means of reducing CVD; increasing intake of vegetable sources, especially extra-virgin olive oil, is more strongly supported but requires confirmation in long-term trials.¹¹²

Polyunsaturated Fatty Acids

Dietary PUFAs include n-6 PUFA, principally LA (18:2 n-6) from vegetable oils; n-3 PUFA, including alpha-linoleic acid (ALA, 18:3 n-3) from plants (e.g., flaxseed, canola, walnuts, soybeans); and eicosapentaenoic acid (EPA, 20:5 n-3) and docosahexaenoic acid (DHA, 22:6 n-3) from seafood. LA and ALA are essential fatty acids that cannot be synthesized by humans. Humans also synthesize relatively little EPA and even less DHA,²⁵ so seafood intake is their major source. The ratio of n-6 to n-3 fatty acids is not a useful metric of health effects when compared with absolute intake of these dietary fats.^{113,114}

Linoleic Acid

LA typically accounts for greater than 90% of dietary PUFAs. The evidence that LA lowers risk for CHD is robust. When compared with carbohydrates, LA lowers LDL-C and TGs, raises HDL-C, and improves the total/HDL-C ratio.⁹⁵ In a pooled analysis of 11 cohorts, greater PUFA intake, in place of SFAs, was associated with a lower incidence of CHD (for each 5% E; RR, 0.87; 95% confidence interval, 0.77 to 0.97).¹⁰³ These observational findings are nearly identical to those of randomized clinical trials, in which increasing PUFAs in place of SFAs reduced CHD events (see Fig. 46-3).⁹⁵ Effects on the total/HDL-C ratio and the results of observational studies each suggest that replacing carbohydrates with PUFAs would have very similar benefits as replacing SFAs.^{93,95,115} Thus, increased intake of PUFA-rich vegetable oils, especially those also containing ALA (see the next section), in place of either SFAs or carbohydrates is a recommended strategy to lower risk for CHD. Some trials and observational studies suggest that LA intake also produces anti-inflammatory or insulin-sensitizing effects, but findings have been mixed,^{106,114,116} and further investigation of these endpoints is needed.

Alpha-Linoleic Acid

ALA is an available and inexpensive plant source of n-3 PUFAs; benefits in people with CVD, if confirmed, would be very important. Ecologic studies suggest benefits of increasing ALA intake in populations with low overall n-3 PUFA intake.¹¹⁷ Yet findings in trials of risk markers, such as platelet function, inflammation, endothelial

TABLE 46-1 Food-Based Components of Dietary Patterns That Improve Cardiometabolic Health*

RECOMMENDATION	GOAL	SERVING SIZES
Consume More		
Fruits	3 servings per day	About 100 g, e.g., 1 medium-sized fruit; ½ cup of fresh, frozen, or canned fruit; ¼ cup of dried fruit; ½ cup of 100% juice. Goals should not be met with juice alone
Vegetables	3 servings per day	About 100 g, e.g., 1 cup of raw leafy vegetables; ½ cup of cut-up raw vegetables, cooked vegetables, or 100% juice. Limit potatoes to ½ cup or less per day
Whole grains [†]	3 servings per day in place of refined grains	About 50 g, e.g., 1 slice of whole grain bread; 1 cup of high-fiber whole grain cereal; ½ cup cooked whole grain rice, pasta, or cereal
Nuts	4-5 servings per week	About 28 g (1 oz)
Fish and shellfish	2+ servings per week, preferably oily	About 100 g (3.5 oz). Goals should not be met with commercially prepared deep-fried or breaded fish
Dairy products [§]	2-3 servings per day	1 cup of milk or yogurt; 1.5 oz of cheese
Vegetable oils	2-6 servings per day	About 1 teaspoon of oil, e.g., in cooking or salad dressing, or 1 tablespoon of vegetable spread
Consume Less		
Foods containing partially hydrogenated vegetable oils (trans fat)	Avoid intake	
Refined grains and starches		
Processed meats (e.g., bacon, sausage, hot dogs, processed deli meats)	Avoid intake or at most modest intake, e.g., up to 2 servings per week	About 100 g (3.5 oz)
Sugar-sweetened beverages, sweets, and bakery foods	Avoid intake or at most modest intake, e.g., up to 5 servings per week	8 oz of soda; 1 small cookie, doughnut, or muffin; 1 slice of cake or pie
Alcohol	Up to 2 drinks daily for men, 1 drink daily for women	5 oz wine, 12 oz beer, 1.5 oz spirits
Energy balance	Eat healthy foods as above, reduce portion sizes, eat fewer fast-food and prepared meals, increase physical activity, limit TV watching, and ensure adequate (8+ hours) sleep	

*Adapted from the evidence described in this chapter, together with U.S. Department of Agriculture and American Heart Association guidelines.^{99,100} Food-based recommendations can facilitate communication and translation to individual patients and populations. Dietary patterns containing these components are naturally higher in fiber, antioxidants, minerals, and phytochemicals and lower in salt, saturated fat, and trans fat.

[†]Based on a 2000-kcal/day diet. Servings should be adjusted accordingly for higher or lower energy consumption.

[‡]Or potentially beans (legumes), although evidence for equivalent effects is limited. No uniform definition exists for defining healthy whole grain foods, thus making such characterization particularly challenging. A practical rule of thumb for selecting grain or carbohydrate-rich products is to consume foods containing less than 10 g of total carbohydrate per each 1 g of fiber per serving (<"10:1 ratio"), based on the Nutrition Facts Panel.¹²

[§]Based on indirect lines of evidence; most guidelines recommend low-fat dairy products.

function, and arterial compliance, and observational studies of its association with CVD and DM endpoints have been mixed and inconclusive.^{24,28,118,119} Few trials of events have been reported; one trial in the 1960s demonstrated no significant change in CHD events with ALA supplementation, but follow-up was just 1 year.¹²⁰

Eicosapentaenoic Acid and Docosahexaenoic Acid

Controlled trials have demonstrate benefits of EPA plus DHA (fish oil) on heart rate, BP, TG levels, cardiac function, and possibly inflammatory responses, endothelial function, and autonomic tone.²⁴ Although several recent individual trials have not found significant benefits, meta-analyses of observational studies and randomized clinical trials have demonstrated that EPA plus DHA intake reduces CHD mortality (see Fig. 46-3),^{13,24-26} in agreement with evidence from dog and primate models of ischemia-induced ventricular fibrillation.²⁴ The dose-response relationship for preventing CHD-related death appears to be nonlinear, with substantial benefits achieved with up to approximately 250 mg/day of dietary EPA plus DHA and little additional benefit thereafter.²⁵

Short-term (typically 6 to 12 months) fish oil supplementation does not appear to have substantial antiarrhythmic benefits in patients with established recurrent arrhythmias, such as recurrent ventricular tachyarrhythmias or atrial fibrillation,^{121,122} and perioperative use

does not reduce postoperative atrial fibrillation after cardiac surgery.^{122,123} Longer-term fish oil use reduced mortality in a large trial of heart failure patients receiving maximal medical therapy.¹²⁴ Some observational studies suggest benefits of fish intake on incident atrial fibrillation, nonfatal MI, and ischemic stroke, but intervention trials have not established these benefits (see Fish, above).²⁴⁻²⁶ Fish oil supplementation does not appreciably affect insulin resistance,¹²⁵ and dietary intake and circulating levels have heterogeneous and inconsistent relationships with incident DM.²⁸

EPA and DHA may each have some different or complementary effects, but such evidence remains preliminary; combined intake appears to be most prudent.¹²⁶ For reducing CHD death, modest dietary intake (≈250 mg/day EPA plus DHA or one to two servings per week of oily fish) is advisable. For patients who wish to augment their omega-3 intake, have previously suffered an MI, or do not consume seafood, fish oil supplementation (≈1 g/day) is reasonable given no harm and its potential benefit.²⁴

Trans Fatty Acids

Trans fatty acids (TFA), or unsaturated fats with one or more double bonds in a *trans* configuration, constitute 20% to 50% of the fatty acids in partially hydrogenated oils, which are used in baked goods, deep-fried foods, packaged snacks, and shortening. TFA

consumption is consistently associated with higher risk for CHD and sudden death (see Fig. 46-2).^{13,127} The small amounts of “natural” TFAs found in the meat and milk of ruminants (e.g., cow, sheep, goat; formed by gut microorganisms) contribute minimally to diet (<0.5% E) and are not associated with risk for CVD.¹²⁷ In trials, TFA intake raises LDL-C, TGs, and lipoprotein(a); lowers HDL-C; and increases the total/HDL-C and apo B/apo A-I ratios; most such effects occur whether TFAs replace SFAs, MUFAs, or PUFAs.¹²⁸ TFAs may also promote inflammation, endothelial vasodilator dysfunction, insulin resistance, visceral adiposity, and arrhythmia, although the strength of evidence for these non-lipid-related effects varies.^{129,130} In sum, the implicated pathways suggest mechanisms related to adipocyte dysfunction and insulin resistance. Emerging evidence suggests that 18-carbon TFAs, especially trans 18:2 isomers, may be most adverse. Because industrial TFAs are food additives with clear adverse effects, their elimination is a public health priority.^{131,132}

Dietary Cholesterol

Dietary cholesterol raises both LDL-C and HDL-C, thereby resulting in a small net effect on the total/HDL-C ratio. In animal models, dietary cholesterol is proatherogenic. Yet in long-term prospective studies, neither dietary cholesterol nor its major sources (e.g., eggs, shellfish) have been associated with incident CHD or stroke, other than a protective association with hemorrhagic stroke.^{13,133,134} In patients with DM, however, higher dietary cholesterol is associated with higher risk for CHD,¹³⁴ and with a higher incidence of DM.^{135,136} In sum, the evidence suggests that dietary cholesterol has minor effects on CVD in the general population but may increase CVD in diabetic patients and also possibly hasten the onset of DM.

Protein

The effects of dietary protein on CVD are understudied. In short-term trials, eating protein-rich foods in place of carbohydrate-rich foods improves BP, TGs, and LDL-C.^{9,137,138} Just a few prospective cohorts have reported on total protein intake and CHD events, with generally null results¹³⁹; this is unsurprising given the divergent effects of various protein-rich foods. Thus, dietary protein per se is far less relevant for CVD than the specific types of foods consumed and overall diet patterns. In a few cohorts, protective associations of animal protein intake on risk for hemorrhagic stroke have been noted,¹⁴⁰ but this could be confounded by the effects of dietary cholesterol.

MICRONUTRIENTS

Sodium

In North America and Europe, most (≈75%) sodium comes from packaged foods; in Asian countries, most sodium is added at home or derived from soy sauce.¹⁴¹ Sodium raises BP, with stronger effects in older persons, hypertensive individuals, and blacks,⁵ and induces BP-independent damage to renal and vascular tissue (see also Chapter 43).¹⁴² Observational studies of dietary sodium and CVD have shown mixed findings, but methodologic limitations may explain much of the discrepancies.^{143,144} In meta-analyses, higher sodium intake is associated with incident total stroke, stroke mortality, and CHD mortality.¹⁴⁵ Post hoc long-term follow-up of sodium reduction trials supports these findings.¹⁴⁶ Even though the optimal lowest intake remains uncertain—current guidelines range from 1200 to 2400 mg/day—evidence is convincing that high intake is harmful, and reducing sodium to no more than approximately 2 g/day is a major priority for prevention of CVD.^{131,132,143,144} In addition, a Mediterranean or DASH-type diet (Dietary Approach to Stop Hypertension, e.g., a diet richer in fruits, vegetables, and nuts) attenuates and a typical Western diet exacerbates the effects of sodium on BP (see Dietary Patterns); this interaction is related, at least partly, to the protective effects of dietary potassium.¹⁴⁷

Other Minerals

Vegetables, fruits, whole grains, legumes, nuts, and dairy products are major sources of minerals. In randomized trials, potassium supplementation modestly lowered BP, with stronger effects in hypertensive individuals and when dietary sodium intake was high. Consistent with these benefits, potassium-rich diets are associated with lower risk for CVD, especially stroke.¹⁴⁷ In short-term trials, calcium and magnesium supplements also modestly lowered BP, although with substantial heterogeneity among studies. However, calcium supplements with or without vitamin D significantly increased the risk for MI in long-term randomized trials.¹⁴⁸ In observational analyses, dietary and blood magnesium are inversely associated with CVD, especially fatal CHD¹⁴⁹; long-term trials have not been performed. The evidence supports the importance of potassium-rich foods in reducing CVD; mineral supplements cannot yet be recommended.

Antioxidants and Vitamins

B vitamins (e.g., thiamin) are derived from the diet, and are water soluble and excreted renally. B vitamin deficiency is a known cause of cardiomyopathy (beriberi) in developing countries, and emerging evidence suggests that patients with chronic heart failure may commonly have lower vitamin B levels.^{150,151} Whether this deficiency is related to poor nutritional status, to diuretic-induced urinary loss, or to other metabolic causes—or whether replacement improves clinical outcomes—remains unknown.

Several dietary vitamins and nutrients have been associated with lower risk for CVD in observational studies, but multiple trials of supplements, including folate, B vitamins, beta-carotene, vitamin C, vitamin E, and selenium, have shown no significant effects on progression of atherosclerosis or CVD events (see also Chapter 42).^{7,13} Most of these trials, for reasons of power, evaluated patients with established CVD or clinical risk factors, whereas most observational studies evaluated generally healthy individuals. Thus, discrepancies in findings could partly be related to different periods of biologic sensitivity—that is, some vitamins and nutrients could be important only early in the course of disease. Such explanations require confirmation in prospective studies and trials. Discrepancies between observational studies and supplement trials may also be related to residual bias in observational studies from other lifestyle behaviors (i.e., the benefits observed are not due to diet) or be attributable to other nutritional factors (i.e., the benefits observed are due to diet but not to the specific identified vitamins or nutrients). Diets higher in beta-carotene and other vitamins, for example, are often rich in fruits and vegetables that contain multiple other beneficial factors, including other antioxidants, minerals, phytochemicals, and dietary fiber, as well as having replacement effects for less healthy foods. Thus, isolating one or even several components would be unlikely to produce similar effects as those achieved by consuming the whole food, as seen in short-term trials of fruits/vegetables versus supplements.

Although observational studies have found links between higher plasma vitamin D, largely driven by sun exposure, and risk for CVD, large trials of vitamin D supplements have shown no benefits.¹⁵²⁻¹⁵⁴ If higher plasma vitamin D proves to lower risk for CVD, brief sun exposure, as opposed to dietary intake, can efficiently provide such levels. Marine n-3 PUFAs represent an exception to the discordance between observational studies and supplement trials of CVD events (see Eicosapentaenoic Acid and Docosahexaenoic Acid; Fish). Overall, both observational studies of individuals with habitual fish intake and controlled trials of fish oil supplements show similar effects on risk factors for CVD and provide evidence for reduced mortality from CVD.

Flavonoids

Flavonoids are bioactive polyphenols and include flavonols (in onions, broccoli, tea, and various fruits), flavones (in parsley, celery,

and chamomile tea), flavonones (in citrus fruits), flavonols such as catechins and procyanidins (in cocoa, apples, grapes, red wine, and tea), anthocyanidins (in colored berries), and isoflavones (in soy).^{65,155} In laboratory studies and randomized trials, flavonoid-rich cocoa lowers BP and improves endothelial function, insulin resistance, and blood lipids.^{65,156} BP lowering occurs with as little as 6.3 g/day (30 kcal/day) of dark chocolate, increases over time, and correlates with increased endothelial nitric oxide production.¹⁵⁷ The latter mechanism suggests potential benefits beyond lowering BP. A few short-term trials of other dietary sources (e.g., tea, red wine, grapes) or specific flavonoid extracts have not consistently observed improved BP, lipid levels, or endothelial function.⁶⁵ A limited number of observational studies evaluating total or selected dietary flavonoids have reported a lower risk for cardiometabolic events,^{158,159} but no long-term clinical trials have been conducted. The heterogeneity of specific flavonoids and their dietary sources limits inference for class effects, but the physiologic benefits of cocoa provide a strong impetus for further study.

ENERGY BALANCE

Energy balance, or calories expended versus calories consumed, is the principal determinant of weight gain and adiposity. Calorie expenditure is influenced by physical activity, body size, muscle mass, age, and sex, which together with goals for weight loss, gain, or stability, determine the need for dietary calories. Some individuals may consume more calories but have neutral or negative energy balance (because of high expenditure of calories), whereas others may consume fewer calories but have positive energy balance (because of low expenditure of calories). The metrics of weight or adiposity provide the most practical tool to assess energy balance.

Multiple factors influence energy balance. Societal and environmental determinants include education, income, and race or ethnicity; safety from crime; the presence of fast-food restaurants, grocery stores, parks or open spaces, and walking or biking paths; and advertising, social norms, and work and home dynamics.^{10,45,160} Ultimately, these influences act through changes in diet and/or activity to influence adiposity. Where data are available, the obesity epidemic appears to principally be related to increased energy intake in high-income nations and to both increased intake and decreased expenditure in low- and middle-income nations⁴⁵ (see also Chapter 1).

Both diet quantity and quality influence energy intake. Factors linked to excess consumption include larger portion sizes; more frequent intake of prepared foods; higher intake of SSBs, potatoes, refined grain, desserts, meat, and trans fat; and lower intake of fruits, vegetables, whole grain, nuts, and yogurt.^{10,45} More time watching television and lower average sleep duration are also associated with energy imbalance and adiposity, with evidence that the effects may be related more closely to changes in energy intake than to expenditure.^{10,45}

In mostly short-term trials of ad libitum diets not designed to evaluate weight, lower-fat diets are associated with marginally lower weight loss (<0.01 kg/yr).¹⁶¹ However, in carefully controlled trials intended to assess the effects of macronutrient composition on weight, higher-fat, lower-carbohydrate diets led to similar reductions in weight and modest but statistically significant improvements in blood cholesterol levels.¹⁶² Similarly, the total fat content of foods has little relationship to long-term weight gain.¹⁰

Habitual excess energy intake as low as approximately 50 kcal/day is sufficient to explain the gradual weight gain seen in most individuals.⁴⁵ This makes unintended weight gain very easy, but also means that modest lifestyle and environmental changes can attenuate or reverse such energy gaps and adiposity.

DIETARY PATTERNS

The study of individual nutrients and foods provides important information on biologic pathways and health effects, but growing

evidence indicates that overall dietary quality is equally relevant. Several diet patterns, including Mediterranean-type, DASH-type, and Prudent diets, have significantly reduced risk factors for CVD in controlled trials and have been linked to a lower onset of CHD, stroke, and DM in prospective cohorts.^{7,99} A Mediterranean-type diet also reduced CVD events in comparison to low-total fat and/or low-SFA diets in a small randomized trial of post-MI patients¹⁰⁹ and a large randomized trial of patients with risk factors for CVD.¹¹⁰ Rather than targeting single risk factors, overall diet patterns improve multiple pathways of risk, including BP, glucose-insulin homeostasis, blood lipids, inflammation, endothelial function, arrhythmic risk, and possibly coagulation and thrombosis.

These dietary patterns share several characteristics that highlight the key features of a cardiometabolically healthy diet (see Table 46-1),⁷ including more minimally processed foods such as fruits, vegetables, whole grains, and nuts; higher intake of fish; modest intake of dairy products and vegetable oils; and lower intake of SSBs and processed, energy-dense, and deep-fried food. Moderate intake of unprocessed meats, poultry, and alcohol can also be part of a healthier food-based dietary pattern. Such diets are naturally higher in fiber, antioxidants, minerals, phytochemicals, and unsaturated fats and lower in salt, TFAs, and SFAs. Appropriate caloric intake and physical activity are also critical for preventing adiposity and DM, as supported by the diet pattern described above, as well as by modest portion sizes, limited television watching, and adequate sleep.¹⁰ A focus on the overall diet pattern rather than on individual foods or nutrients can be effective for both individual counseling and population recommendations by facilitating communication, allowing individual flexibility and preferences in diet choices, and increasing the impact on health because of the combined benefits of multiple modest changes.

CHANGING BEHAVIOR

For reducing cardiometabolic risk, key dietary factors can be prioritized (see Table 46-1). Relative to most clinical interventions, dietary improvement can be low risk, low cost, and broadly available—advantages that are highly germane to prevention and treatment of disease. Translation of these dietary priorities into action—at the practitioner, health care system, community, and policy levels—is essential. The global pandemics of obesity, DM, and CVD highlight the substantial health and economic costs of an undesirable diet and the imperatives of emphasizing nutrition in clinical care and policy. Several factors have limited translation of this knowledge to action, including evolving messages and confusion about specific dietary priorities, uncertainty regarding effective methods for changing behavior, and inadequate clinical tools to monitor diets efficiently. Fortunately, advances in research have addressed these challenges.^{7,160,163} Both individual- and population-based strategies can be effective.^{160,163} By combining such methods, many high-income countries have substantially reduced tobacco use and promoted other healthy behavior such as seat belt, child seat, bike helmet, and sun-screen use. Because modest dietary differences can substantially alter risk for disease at the population level, large changes are frequently unnecessary.

Individual-Based Strategies

Key features of successful individual-based (e.g., clinical) changes in behavior include setting of specific proximal goals, establishing self-monitoring, scheduling regular follow-up, providing feedback (in person, by telephone, or electronically), and providing long-term support (family, friends, peers). Additional evidence-based measures include increasing self-efficacy (patients' perception that they can successfully change their behavior) and using motivational interviewing (when patients are resistant or ambivalent about changing their behavior). Complementary systems strategies should be instituted by providers to support and facilitate efforts to change behavior,¹⁶⁰ including additional visit time to focus on changes in behavior;

sufficient financial and other incentives for health promotion; education for providers on dietary priorities and behavioral interventions; and efficient electronic systems for scheduling and tracking initial visits and regular follow-up contacts for behavioral changes, for helping assess, track, and report on lifestyle, and for providing feedback to both providers and patients. Integrated systems can provide coordinated care by multidisciplinary teams, including physicians, nurse practitioners, dietitians, physical activity specialists, and social workers. In addition, reimbursement guidelines and incentives should reward efforts to change behavior, and practice goals and quality benchmarks should incorporate key dietary interventions and targets.

Emphasizing foods that should be consumed for good health (see Table 46-1) instead of just foods that should be avoided may achieve greater success. Familiarity with selected evidence-based foods and dietary patterns rather than comprehensive nutritional expertise is sufficient. Until standardized questionnaires and/or biomarker panels are developed and evaluated, practitioners can perform simple

office-based assessments to ask about selected dietary habits. Because targeted goals are most effective, providers can focus on selected dietary priorities (see Table 46-1), tailored as needed for specific risk factors or disease conditions (see Table 46-2). Incomplete success should not dissuade efforts. Although compliance with both lifestyle changes and medications is incomplete, such strategies, even imperfectly implemented, improve clinical outcomes.¹⁶⁴

Population-Based Strategies

Dietary interventions at the school, workplace, community, regional, and national levels can have a meaningful and sustained impact. Evidence-based strategies are available across a range of domains, including media/education, product labeling/information, school/workplace, local environmental change, economic incentive, and direct ban/mandate approaches.¹⁶⁰ Examples include sustained media campaigns focused on increasing specific healthful foods;

TABLE 46-2 Effects of Food and Nutrients on Specific Cardiometabolic Risk Factors and Disease Endpoints

	STRENGTH OF EVIDENCE FOR BENEFITS			INSUFFICIENT EVIDENCE FOR EFFECTS
	Convincing	Probable	Possible	
Hypertension	Higher intake of Mediterranean- or DASH- type dietary pattern Dietary fiber Fruits and vegetables Fish or fish oil Cocoa or dark chocolate Potassium Lower intake of Sodium	Higher intake of Calcium Soy foods Lower intake of caffeine	Higher intake of Whole grains Magnesium Vitamin D Soy protein MUFAs in place of SFAs	Isoflavones Coffee or tea PUFAs or carbohydrates in place of SFAs
High LDL-C	Higher intake of MUFAs or PUFAs Dietary fiber Fruits and vegetables Green tea Soy protein Lower intake of Trans fat SFAs 12:0-16:0 Dietary cholesterol	Higher intake of Dairy Whole grains Lower intake of unfiltered coffee		
Atherogenic dyslipidemia (low HDL-C, high triglycerides)	Higher intake of Mediterranean- or DASH- type dietary pattern MUFAs or PUFAs Fish or fish oil Lower intake of Simple or complex refined carbohydrates (high GI or GL) Trans fat	Higher intake of dairy	Higher intake of fruits and vegetables	
Insulin Resistance, Type 2 Diabetes	Higher intake of whole grains Lower intake of Processed meats Moderate alcohol use	Higher intake of PUFAs or vegetable oils Dairy Lower intake of simple or complex refined carbohydrates (high GI or GL)	Higher intake of Fruits and vegetables MUFAs or PUFAs in place of SFAs Coffee Lower intake of Dietary cholesterol Trans fat	Carbohydrates in place of SFAs Unprocessed meats Fish or fish oil Tea
Obesity	Higher intake of whole unprocessed foods (e.g., whole grains, vegetables, nuts, fruits) Lower intake of sugar- sweetened beverages	Higher intake of dietary fiber Lower intake of Large portion sizes Simple or complex refined carbohydrates (high GI or GL) Energy-dense foods (high carbohydrate/low fiber or high fat) Less television watching	Higher intake of green tea Lower intake of Deep-fried foods Meals from quick service restaurants Trans fat Greater sleep duration	Total fat (% E) SFAs, MUFAs, or PUFAs

Continued

TABLE 46-2 Effects of Food and Nutrients on Specific Cardiometabolic Risk Factors and Disease Endpoints—cont'd

	STRENGTH OF EVIDENCE FOR BENEFITS*			
	Convincing	Probable	Possible	INSUFFICIENT EVIDENCE FOR EFFECTS
Systemic inflammation	Higher intake of fruits and vegetables	Higher intake of Mediterranean- or DASH-type diet pattern Whole grains Fish oil (supplements) Lower intake of TFAs	Higher intake of Fish, fish oil (diet), ALA PUFAs Nuts Lower intake of simple or complex refined carbohydrates (high GI/GL)	SFAs or MUFAs
Coronary heart disease	Higher intake of Fish or fish oil (CHD mortality) PUFAs in place of SFAs Mediterranean- or DASH-type dietary pattern Fruits and vegetables Whole grains Nuts Dietary fiber Lower intakes of: Trans fat Processed meats Moderate alcohol use	Lower intake of Simple or complex refined carbohydrates (high GI or GL) Dietary cholesterol in patients with diabetes	Higher intake of Fish or fish oil (nonfatal CHD) Dairy Legumes ALA MUFAs in place of SFAs Vitamin D Lower intakes of: Sodium Unprocessed meats Dietary cholesterol in patients without diabetes	Total fat (% E) Carbohydrate in place of SFAs Antioxidant or vitamin supplements Coffee or tea
Ischemic stroke	Higher intake of Mediterranean- or DASH-type dietary pattern Fruits Whole grains	Higher intake of fish Lower intake of sodium	Higher intake of Vegetables SFAs Fish oil Tea Lower intake of processed meats	ALA Antioxidant or vitamin supplements
Hemorrhagic stroke		Higher intake of Whole grains Mediterranean- or DASH-type dietary pattern Lower intake of sodium	Higher intake of SFAs Animal protein Tea	Fish or fish oil
Heart failure [†]	Lower intake of heavy alcohol use		Higher intake of Mediterranean- or DASH-type dietary pattern Whole grains Fish Moderate alcohol use	
Atrial fibrillation		Lower intake of heavy alcohol use	Higher intake of fish or fish oil	

*Strength of evidence defined by Bradford-Hill and World Health Organization criteria.¹⁰¹ For most dietary factors, evidence is derived from controlled trials of risk factors plus long-term prospective cohorts of disease endpoints. For fish/EPA+DHA, omega-6 PUFAs, and total fat intake, evidence is also derived from randomized trials of clinical endpoints.

[†]Incidence. Limited data on dietary treatment for secondary prevention, except for one large randomized trial of EPA+DHA supplementation in which reduced total mortality was reported, and clinical experience with sodium restriction to prevent fluid overload.

comprehensive, multicomponent school and workplace programs; taxation to reduce less healthy foods and subsidies to increase more healthy foods, especially for youth, lower socioeconomic groups, and other price-sensitive populations; regulation of advertising and marketing to children; and direct mandates to increase healthier foods (e.g., vegetable oils) or reduce unhealthy nutrients (e.g., TFAs, sodium).¹⁶⁰

Population-based interventions are most successful when various stakeholders—community members, policy makers, and advocacy groups—participate throughout planning, implementation, and maintenance. Multicomponent strategies, such as integrated approaches that include upstream policy measures, midstream media campaigns, and downstream community approaches, may be especially effective. Population-based strategies complement individual-based approaches and can also reduce the social and racial disparities caused by clustering of suboptimal diet habits, local environments, and risk factors for disease.

HISTORICAL PERSPECTIVE

Until the early 1950s, standard treatment of myocardial infarction (MI) was several weeks of hospitalization followed by months of restricted physical activity. Exercise-based cardiac rehabilitation was developed to reverse the physical deconditioning produced by this restriction of physical activity. Exercise training was central to this process and was one of the few interventions that reduced exertional angina pectoris in the era before beta-adrenergic blocking agents and coronary artery revascularization procedures.¹

Shorter hospitalizations, along with effective medications and procedures to treat myocardial ischemia, have changed cardiac rehabilitation programs. Exercise training is still important, but education and counseling to improve psychological well-being, reduce cigarette smoking, and increase adherence to medications and diet are now key components of the rehabilitation effort.² U.S. Centers for Medicare & Medicaid Services (CMS) guidelines reflect these changes and stipulate that “cardiac rehabilitation programs must be comprehensive and...include a medical evaluation, a program to modify cardiac risk factors...prescribed exercise, education, and counseling.” Consequently, cardiac rehabilitation programs are now often referred to as “cardiac rehabilitation/secondary prevention programs.”² The American Heart Association (AHA) and American College of Cardiology Foundation (ACCF) recommend comprehensive cardiac rehabilitation programs (class I indication) for patients who have undergone percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting (CABG), who have suffered an acute cardiac syndrome, or who have stable angina pectoris or peripheral vascular disease.³ This recommendation received the highest level of evidence (level A) for all conditions except angina (level B).³ The CMS also considers comprehensive cardiac rehabilitation “reasonable and necessary” for patients after valve surgery and heart or heart and lung transplantation.⁴ They proposed using referral to cardiac rehabilitation as a core performance measure for the management of patients with coronary disease and after cardiac surgery starting in January 2014, with an impact on hospital reimbursement in 2015.⁵ Consequently, interest in cardiac rehabilitation will probably increase in the near future.

Exercise training is central to most cardiac rehabilitation/risk reduction programs because it increases exercise capacity and

reduces exercise-induced cardiac ischemia and angina, but even programs without an exercise component may reduce recurrent cardiac events. A meta-analysis of 63 randomized secondary prevention trials that included 21,295 patients with coronary artery disease (CAD) noted a 15% reduction in mortality, but the reductions in mortality and recurrent MI were similar for programs that involved exercise only, exercise and risk factor education and counseling, and risk factor education and counseling alone⁶ (Table 47-1). Because risk factor reduction is discussed elsewhere in detail (see also Chapters 42, 44, and 45), this chapter specifically addresses exercise training in the rehabilitation process.

BASIC PRINCIPLES OF EXERCISE PHYSIOLOGY AND EXERCISE TRAINING¹

Maximal Oxygen Uptake

Skeletal muscle contains only small amounts of energy for immediate use. Aerobic and resistance exercises (Table 47-2) increase the body's oxygen requirements to supply energy to the exercising muscle. The amount of energy used during effort is measured indirectly as the amount of O₂ consumed—referred to as ventilatory oxygen consumption (\dot{V}_{O_2}). Rearranging the Fick equation—cardiac output (Q) = \dot{V}_{O_2} / arterial – venous O₂ difference (A-V O₂ Δ)—demonstrates that \dot{V}_{O_2} is the product of Q and A-V O₂ Δ. Thus, the metabolic demands of exercise are met by increasing O₂ delivery through increases in Q, which in turn is the product of heart rate (HR) and cardiac stroke volume (SV), as well as through increases in A-V O₂ Δ. A-V O₂ Δ increases during exercise by redistribution of blood flow from nonexercising tissue (such as the kidneys and splanchnic bed) to exercising muscle, by increased O₂ extraction in the exercising muscle, and by hemoconcentration as a result of plasma fluid losses into the interstitial space of exercising muscle. The increase in Q during exercise is tightly coupled to the increase in \dot{V}_{O_2} such that a 1-liter increase in \dot{V}_{O_2} elicits approximately a 6-liter increase in Q. Maximal exercise capacity is measured as $\dot{V}_{O_{2max}}$ —the maximal amount of oxygen that an individual can transport during exercise before being limited by fatigue or dyspnea. $\dot{V}_{O_{2max}}$ is a highly stable and reproducible measure of exercise capacity, expressed as either an absolute value in liters per minute or relative to body weight as milliliters per kilogram per minute. The maximal increase in A-V O₂ Δ is fixed at approximately 15 to 17 vol-%. Because the exercise work rate determines \dot{V}_{O_2} , which is the product of Q and A-V O₂ Δ, and because the maximal A-V O₂ Δ is relatively fixed, $\dot{V}_{O_{2max}}$ is an indirect measure of maximal cardiac pump capacity, or maximal Q and SV.

TABLE 47-1 Reductions in Mortality and Recurrent (“New”) Myocardial Infarction by Cardiac Rehabilitation Program Characteristics at 12 Months

PROGRAM CHARACTERISTIC	MORTALITY	95% CI	NEW MI	95% CI
All programs	−15%	−6% to −33%	−17%	−6% to −26%
Exercise only	−28%	−5% to −46%	−24%	+1% to −43%
Exercise and RF modification	−12%	+4% to −26%	−38%	−3% to −56%
RF modification only	−13%	−1% to −24%	−14%	+3% to −28%

CI = confidence interval; RF = risk factor.

TABLE 47-2 Terms to Describe Exercise

<i>Physical activity</i> —Any body movement
<i>Exercise</i> —Physical activity to the point of stress and strain
<i>Aerobic exercise</i> —Exercise that primarily stresses the oxygen transport system and includes activities such as walking, jogging, swimming, and cycling
<i>Resistance exercise</i> —Exercise that primarily stresses the muscular skeletal system and includes weightlifting
<i>Exercise training</i> —Exercise performed repetitively to increase the performance capacity of the cardiovascular system (aerobic exercise training) or muscular skeletal system (resistance exercise training)

From Thompson PD: Exercise prescription and proscription for patients with coronary artery disease. *Circulation* 112:2354, 2005.

Myocardial Oxygen Uptake

Myocardial O_2 demand (MO_2) can be estimated as the product of HR and systolic blood pressure (SBP)—the so-called double product. Although the absolute exercise work rate determines $\dot{V}O_2$ and Q , increases in HR and SBP are determined by the exercise $\dot{V}O_2$ requirement as a percentage of $\dot{V}O_{2max}$. Consequently, for any absolute exercise level, an individual with a larger $\dot{V}O_{2max}$ uses less maximal capacity and has a lower HR and SBP response to exercise. The key point is that MO_2 is not determined solely by the external exercise work rate, but by the exercise work rate *relative* to maximal exercise capacity.

Ventilatory Threshold

Expired carbon dioxide ($\dot{V}CO_2$) also increases as the exercise work rate increases. Increases in $\dot{V}O_2$ and $\dot{V}CO_2$ are parallel early during exercise, but the rate of CO_2 expiration increases more rapidly, and the coupling of $\dot{V}O_2$ and $\dot{V}CO_2$ diverge at what is termed the *ventilatory threshold* (VT). This divergence results from the increase in blood lactic acid, buffering of the lactic acid H^+ ions by bicarbonate, and the subsequent exhalation of additional CO_2 . The VT has also been called the “anaerobic threshold” and OBLA (for “onset of blood lactate accumulation”). As CO_2 stimulates the respiratory drive, the VT is also associated with a nonlinear increase in the respiratory rate and mild dyspnea. The VT occurs at approximately 50% of $\dot{V}O_{2max}$ in non-exercise-trained individuals but at higher levels of the percentage of $\dot{V}O_{2max}$ in exercise-trained subjects. VT is an important measurement of exercise tolerance because it represents the maximal steady work rate that can be maintained during submaximal exercise.

Effect of Cardiac Disease on Exercise Performance

Exercise performance may be normal for age and sex in individuals with cardiac disease. Alternatively, diseases that limit maximal SV, impair the HR response, or cause myocardial ischemia that produces limiting symptoms or a diminished increase in SV may impair

exercise capacity. Medications that limit the HR response to exercise (such as beta-adrenergic blocking agents) or restrictions in physical activity that produce a detraining effect may also contribute to reduced exercise tolerance in cardiac patients.

Effect of Exercise Training on Exercise Performance

The primary effect of either aerobic or strength training is increased exercise capacity. With strength training, the primary adaptation is to increase muscular strength and endurance in the exercise-trained muscle. The principal effect of aerobic exercise training is increased $\dot{V}O_{2max}$. This increase in maximal exercise capacity means that any submaximal work rate requires a lower percentage of $\dot{V}O_{2max}$, thereby reducing the HR and SBP response and MO_2 requirements. Endurance exercise training also increases the absolute VT and VT as a percentage of $\dot{V}O_{2max}$. Multiple adaptations contribute to improvement in exercise tolerance after training, including increases in SV and widening of the A-V O_2 Δ .

The magnitude of the increase in exercise $\dot{V}O_{2max}$ with endurance exercise training depends on multiple factors, including the age of the subject, the intensity and duration of the training regimen, genetic factors, underlying disease states, and whether testing and training use similar exercises. In general, young subjects trained intensively have greater improvement in exercise tolerance. Increases in $\dot{V}O_{2max}$ average 11% to 36% in cardiac rehabilitation patients,⁷ although the response varies with the severity of the underlying disease. Individuals with markedly reduced ventricular function, for example, may achieve much of their increase in exercise capacity by widening the A-V O_2 Δ , whereas increases in cardiac output have been documented with 12 months of exercise training in some cardiac patients.¹ In addition to increasing maximal exercise capacity, endurance exercise training—by virtue of its effects on the VT—increases endurance capacity. This effect is extremely important because increased submaximal exercise endurance capacity reduces dyspnea at submaximal work rates and facilitates the performance of most daily tasks.

EFFECTS OF CARDIAC REHABILITATION AND EXERCISE TRAINING ON MORBIDITY AND MORTALITY IN CARDIAC PATIENTS

Angina Pectoris

Most patients with angina pectoris control their symptoms with medication or eliminate them by undergoing PTCA or CABG. Consequently and with rare exceptions,⁸ much of the evidence that exercise training improves effort tolerance in patients with angina pectoris was obtained before 1990. Exercise training increases exercise time until the onset of angina—or eliminates angina entirely—by at least two mechanisms. First, as discussed earlier, exercise training increases $\dot{V}O_{2max}$, thereby reducing the HR and SBP response to submaximal exercise. This reduction in the double product reduces the MO_2 requirements and delays the onset of angina. Second, exercise training improves endothelial function.⁹ Normal coronary arteries dilate with exercise, whereas atherosclerotic coronary arteries often demonstrate endothelial dysfunction with exercise, as evidenced by failure to dilate or by vasoconstriction. Exercise training reduces endothelial dysfunction, as measured by quantitative coronary angiography during infusion of the endothelial agonist acetylcholine.⁹ Some patients also demonstrate increases in the rate-pressure product at the onset of angina after only a short period of exercise training¹—also suggesting improved endothelial function (Fig. 47-1).

Exercise training is primarily used in patients with angina who are not amenable to coronary interventions, but a clinical trial of 101 men 70 years of age or younger suggested that exercise training is useful in other patients with stable angina.⁸ Subjects were randomly assigned to 1 year of exercise training or to PTCA. They were excluded if the lesion was not suitable for PTCA or if they had high-grade stenosis of

FIGURE 47-1 Changes in exercise tolerance and the onset of angina with exercise training. The HR versus $\dot{V}O_2$ slope is shifted so that any work rate ($\dot{V}O_2$) elicits a slower HR response. Angina is delayed but occurs at the same HR if there is no change in coronary blood flow (CBF) (new angina onset [no Δ CBF]). Angina is delayed but occurs at a higher HR if CBF is increased by improved endothelial function. (Reproduced from Thompson PD: Exercise prescription and proscription for patients with coronary artery disease. *Circulation* 112:2354, 2005.)

the left anterior descending artery, greater than 25% left main stenosis, valvular disease, ejection fraction lower than 40%, MI within 2 months, PTCA or CABG within 12 months, or insulin-dependent diabetes. The exercise training consisted of 2 weeks in the hospital during which six daily 10-minute sessions were performed at 70% of their maximal tolerated HR, followed by daily 20-minute home bicycle ergometer exercise sessions plus a weekly 60-minute supervised session.

Forty-seven subjects in each group completed the trial. The exercise level at the onset of ischemia increased 30% in the exercise-trained subjects and 20% in the PTCA subjects. These differences were not significant, but increases in maximal exercise capacity (20% versus 0%) and $\dot{V}O_{2\max}$ (16% versus 2%) were significantly greater in the exercise-trained subjects. The potential target lesion did not change in the exercise subjects, and only 15% of the PTCA subjects demonstrated restenosis, defined as greater than 50% luminal narrowing at the PTCA site. At 1 year, 88% of the PTCA subjects versus only 70% of the exercise-trained subjects experienced a major cardiovascular event—including MI, stroke, revascularization procedure, or hospitalization for angina ($P = 0.023$) (Fig. 47-2). This study predated the widespread use of drug-eluting stents, but even assuming no in-stent restenosis, the exercise group would still have had a greater event-free survival rate (88% versus 72%, $P = 0.039$). The authors noted that angioplasty treats one culprit lesion whereas exercise training addresses endothelial dysfunction throughout the vascular system. These results cannot be generalized to all subjects with stable angina, but they document that exercise training may be suitable for managing selected patients with angina.

Effect of Cardiac Rehabilitation on Morbidity and Mortality in Patients with Coronary Artery Disease

A systematic review identified 47 studies in which 10,794 patients with MI, CABG, PTCA, or angina were randomly assigned to exercise-based cardiac rehabilitation or to usual care.¹⁰ Total mortality and

cardiovascular mortality were 13% and 26% lower, respectively, at 12 months or more of follow-up, whereas hospital admissions were 31% lower in the first year of the study ($P < 0.05$ for all). Subsequent MI, CABG, or PTCA did not decrease. As discussed earlier, a variety of secondary prevention programs, including those without an exercise component,⁶ can obtain similar results—so non-exercise-related factors such as better adherence to medications, close supervision by the rehabilitation staff, or social support probably contributed to the benefits of the rehabilitation programs.

Cardiac Rehabilitation in Patients after Percutaneous Transluminal Coronary Angioplasty

Few large trials have examined the effects of exercise-based cardiac rehabilitation in patients following PTCA. A retrospective analysis of 2395 patients after PTCA noted an approximately 45% reduction in mortality ($P < 0.001$) in the 40% of patients who participated in cardiac rehabilitation.¹¹ Rehabilitation did not affect recurrent MI or subsequent revascularization, but the reduction in mortality did not differ by sex, age, or PTCA urgency, thus suggesting that cardiac rehabilitation can benefit almost all patients after PTCA. Unfortunately, self-selection bias cannot be eliminated as an explanation for these results, but they agree with the overwhelming theme that cardiac rehabilitation improves clinical outcomes.

Cardiac Rehabilitation in Heart Failure

Until 2009, only meta-analysis support existed for a benefit of exercise in patients with heart failure (HF) (see also Chapter 25).¹² HF-ACTION (Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training) was the first large-scale, adequately powered trial to examine the effect of exercise training on cardiovascular outcomes in patients with stable HF.¹³ HF-ACTION randomly assigned 2331 patients with a left ventricular ejection fraction (LVEF) of 35% or less to an exercise-training group or a control group. Exercise-training subjects were encouraged to participate in 36 supervised

FIGURE 47-2 Event-free survival in 101 carefully selected patients with stable angina randomly assigned to percutaneous coronary intervention (PTCA/stent) or to 1 year of exercise training. Numbers at bottom indicate patients free of events. Event-free survival was significantly better in the exercise-training group (88% versus 70%, $P = 0.02$ by log-rank test). (Reproduced from Hambrecht R, Walther C, Mobius-Winkler S, et al: Percutaneous coronary angioplasty compared with exercise training in patients with stable coronary artery disease: A randomized trial. *Circulation* 109:1371, 2004.)

	146	167		

FIGURE 47-3 All-cause mortality or all-cause hospitalization in HF-ACTION. The hazard ratio was not reduced in the unadjusted data but was statistically significant when adjusted for baseline exercise duration, left ventricular ejection fraction, Beck Depression Inventory II score, history of atrial fibrillation or flutter, and cause of HF. (Reproduced from O'Connor CM, Whellan DJ, Lee KL, et al: Efficacy and safety of exercise training in patients with chronic heart failure: HF-ACTION randomized controlled trial. *JAMA* 301:1439, 2009.)

exercise sessions over a period of 3 months and were transitioned to home exercise, with the goal of exercising five times weekly for 40 minutes. The training target HR was 60% to 70% of the maximum HR reserve, calculated as maximal HR minus resting HR, multiplied by 0.6 to 0.7, and added to resting HR.

The mean duration of follow-up was 3.1 years, with a range of 1 to 4 years. Total mortality (−4%, $P = 0.7$), cardiovascular mortality or cardiovascular hospitalization (−8%, $P = 0.14$), and cardiovascular mortality or hospitalization for HF (−13%, $P = 0.06$) decreased insignificantly more in the exercise-trained group than in the control group. These results were reexamined after adjusting for prespecified confounders, including baseline exercise duration, LVEF, a psychological depression index, and a history of atrial fibrillation or flutter. After this adjustment, total mortality or hospitalization (−11%, $P = 0.03$), cardiovascular mortality or hospitalization (−9%, $P = 0.09$), and cardiovascular mortality or cardiovascular hospitalization (−15%, $P = 0.03$) decreased, thus suggesting that exercise training had beneficial effects in patients with HF (**Fig 47-3**).

HF-ACTION did not have overwhelmingly positive results, but the study probably underestimated the potential benefits of exercise training in patients with HF. The results reported appropriately used an intention-to-treat analysis, but the exercise group had poor compliance. Only 736 subjects (60%) completed the 36 supervised exercise sessions. The investigators attempted to enhance long-term exercise compliance by providing home treadmills or exercise cycles and HR monitors. They also used various adherence optimization strategies. Despite such efforts, peak $\dot{V}O_2$ increased only 4% in the exercise-training group. This effect was short of the 10% increase projected by the study investigators and well below the 17% increase reported in HF patients exercising in supervised sessions.¹²

In contrast, an Italian study in which the rate of adherence to training was reported to be 88% over the 10-year study period demonstrated the potential benefits of exercise training in patients with HF.¹⁴ This study randomly assigned 123 patients with New York Heart Association class II and III HF and an ejection fraction lower than 40% to a formal exercise-training group or to a control group without formal training. The training group trained at 60% of their peak $\dot{V}O_2$

for 2 months and at 70% thereafter. Exercise sessions occurred twice weekly, with participants encouraged to exercise a third time on their own. Most of the training was done in a "cardiac club," which also promoted healthy lifestyles. Peak $\dot{V}O_2$ increased 14.7% in the exercise-training group and decreased 2.5% in the control group after 1 year. At 10 years, peak $\dot{V}O_2$ was 21.8% higher in the exercise-training group. Remarkably, the ejection fraction increased only in the exercise-training group, and this difference appeared only after 5 years into the study (**Fig. 47-4**). Twelve cardiac events occurred in the exercise-trained subjects and 35 in the control subjects—a 45% reduction (95% CI, −28% to −74% reduction; $P < 0.001$) (**Fig. 47-5**). Similarly, 4 deaths occurred in the exercise-training group and 10 deaths in the control group—a 32% reduction (CI, −28% to −70% reduction). These results suggest that prolonged exercise training can profoundly affect clinical outcomes in patients with HF if adherence is strong.

PRACTICAL ASPECTS OF CARDIAC REHABILITATION PROGRAMS

Program Structure

Cardiac rehabilitation programs are divided into three phases based on the patient's clinical status. Phase 1 refers to inpatient programs started soon after the acute cardiac event or intervention. These programs are uncommon presently because of the brevity of most hospital stays, although some European countries have inpatient rehabilitation programs lasting up to several weeks. Phase 1 programs remain useful in mobilizing elderly patients after complicated cardiac events, as well as for many types of patients after cardiac surgery. In the United States, physical therapy departments or dedicated cardiac rehabilitation staff often direct these programs. Phase 1 is also an excellent way to introduce patients to the concept of cardiac rehabilitation and to solicit appropriate referrals. Separate reimbursement for phase 1 programs in the United States is not available because this service, if provided, is included in the charges for the acute event.

Phase 2 refers to physician-supervised outpatient programs in the postdischarge period. Patients in these programs usually exercise three times weekly, for a total of 36 sessions over a period of 3 to 4 months. Other approaches to cardiac rehabilitation—including simple home-based, self-supervised programs; home-based, visiting nurse-supervised programs; and home-based programs with telephone electrocardiographic (ECG) monitoring—have been examined in research settings and compare favorably with standard facility-based programs.¹⁵ Alternative programs are not covered by most insurance carriers, but need to be developed because many patients cannot attend the standard, facility-based programs.¹⁵

Phase 3 refers to non-ECG-monitored maintenance programs. They are provided by the same facilities providing phase 2 programs, but because phase 3 programs do not usually include medical supervision, health clubs and fitness facilities may also provide them. Phase 3 programs are not generally covered by medical insurance in the United States.

Staff Coverage

The standard cardiac rehabilitation program has a physician medical director, a staff nurse, and other nurses or individuals with training in exercise physiology to design the exercise and educational programs and to supervise the exercise sessions. To qualify for Medicare reimbursement in the United States, phase 2 cardiac rehabilitation programs must have a physician medical director. This individual must review and approve a treatment plan for each patient every 30 days.¹⁶ In addition, a supervising physician must be immediately available during the rehabilitation sessions, and patients must have an ECG strip interpreted and mounted in the chart for each session. Definition of the term “immediately available” is open to interpretation but generally means being in the facility and available within moments for any emergency. All cardiac rehabilitation staff must be trained in advanced cardiac life support. A nurse must be available during the exercise rehabilitation sessions to handle emergencies and administer medications. Staffing level recommendations are 1 staff member per 5 participants during phase 2 programs and 1 staff member per 10 to 15 participants during phase 3 sessions.

Design and Administration of the Exercise Training Program

Patients referred to cardiac rehabilitation should undergo a symptom-limited exercise test before entering the program to identify and evaluate any important symptoms, ischemia, or arrhythmias that might require other interventions before exercise training. The exercise test also establishes baseline exercise capacity and determines the maximum HR to prepare an exercise-training prescription. Tests are usually performed with patients taking their usual medications to mimic the HR response likely to occur during exercise training.

A typical exercise training session for cardiac rehabilitation patients consists of 5 minutes of warm-up, followed by at least 20 minutes of aerobic exercise training and 5 to 15 minutes of cool-down. The warm-up session consists of stretching and light calisthenics. Some resistance exercise training using light weights or exercise machines should also be performed, often after the aerobic session and as part of an extended cool-down period. Exercises, including biceps curls, triceps extensions, military presses (for patients without shoulder problems), shoulder shrugs, bent-knee pushups, bent-knee “crunches,” and quarter squats, address most of the major muscle groups and increase patients' ability to perform daily living and work tasks, such as lifting and carrying.

The aerobic exercise—training component is generally performed at 60% to 70% of $\dot{V}O_{2max}$, which corresponds to approximately 70% to 80% of the maximum HR. Some patients require lower training intensities. Although 20 minutes of exercise training is standard, shorter periods have benefit, and longer sessions almost certainly provide additional benefit. Most cardiac rehabilitation programs recommend other activities, such as yard work and walking, on days when patients do not attend supervised sessions.

Exercise testing before starting cardiac rehabilitation is useful, but not all patients—especially those after recent MI—undergo such testing. Patients who did not undergo exercise testing before starting a program can exercise at a HR 20 beats faster than their resting value. Another approach consists of exercising patients at their resting HR, plus a specified additional percentage of their rest HR. For example, during month 1, a patient might exercise at rest HR plus 20% to 30% of rest HR; month 2, rest HR plus 20% to 40% of rest HR; and month 3, rest HR plus 20% to 50% of rest HR. Alternatively, such patients can exercise to the point of mild dyspnea and maintain that level during the training session. As discussed earlier, the onset of dyspnea approximates the VT and is an adequate intensity for a training stimulus. Finally, patients can exercise to a “somewhat hard” level by using number scales designed to estimate the intensity of exertion, such as the modified Borg Scale of Perceived Exertion.

Unsupervised Exercise Training

Many patients cannot attend supervised exercise training sessions but should be advised to exercise for its cardiovascular benefits. Patients without lower limb orthopedic problems should be encouraged to use brisk walking as their exercise training modality. Patients in unsupervised programs should generally be encouraged to exercise to the onset of mild dyspnea for the reasons mentioned earlier. Such an approach obviates the need for pulse monitoring. Many patients either cannot accurately monitor their heart rate or become unduly concerned about pulse irregularities caused by premature atrial or ventricular contractions. Patients exercising on their own can also be encouraged to judge their exercise intensity by using the “talk test”—exercising at the fastest rate that still permits comfortable conversation. This work rate corresponds to the exercise-training range recommended for cardiac patients.¹

OTHER COMPONENTS OF COMPREHENSIVE CARDIAC REHABILITATION

Nutritional, psychological, and vocational counseling, as well as serum lipid, blood pressure, and smoking risk factor management components, are required by Medicare.¹⁷ These components of secondary CAD prevention have critical importance. Addressing issues such as blood pressure and lipid management and smoking cessation often requires balancing the roles of the cardiac rehabilitation staff and the primary care physician. Cardiac rehabilitation personnel generally focus on the counseling aspects of risk factor management. They can also interpret laboratory results and physician instructions and act as patient advocates with their primary health care providers. With lipid management, for example, the rehabilitation staff may evaluate the results from the patient's physician and suggest that the

patient request a more aggressive treatment approach to achieve cholesterol goals.

Programs differ in how they deliver the counseling and education components. Many programs use the time when the patient is on the exercise apparatus to visit and educate. Some programs simply make printed material available to the participants. Other programs use television monitors and either commercially available or locally prepared video programs to deliver the counseling and risk reduction messages. Some programs have replaced exercise sessions with educational programs. Classroom activities can be scheduled creatively in addition to the exercise sessions, thereby allowing participants to choose what education programs best meet their needs.

INSURANCE COVERAGE

Insurance coverage of cardiac rehabilitation activities is important for patients to be able to receive these services. Medicare in the United States¹⁷ provides reimbursement for patients who have stable angina pectoris, have suffered acute MI, or have undergone CABG, cardiac valve repair or replacement, PTCA, or heart or heart-lung transplantation within the previous 12 months. Many private insurers follow the Medicare reimbursement procedures. Routine coverage is for a total of 36 exercise sessions, although Medicare provides coverage for up to 72 sessions in some instances.¹⁵ Medicare has not historically covered cardiac rehabilitation for HF, but has proposed to initiate such coverage, possibly in 2014. Patients will qualify if they have an ejection fraction of less than 35% and symptoms despite at least 6 weeks of optimal medical therapy.¹⁸ Insurance coverage in other parts of the world varies greatly.

CURRENT CHALLENGES FOR CARDIAC REHABILITATION

The major problem with exercise-based cardiac rehabilitation currently is its underutilization. Only 14% to 35% of MI survivors and approximately 31% of patients following coronary revascularization are referred to cardiac rehabilitation programs.¹⁵ Women, older patients, and minorities—the very groups at greatest risk for recurrent events—have especially low referral rates.¹⁵ Physician endorsement of cardiac rehabilitation is one of the most important predictors of participation.¹⁵ Why physicians do not routinely refer patients to rehabilitation is unclear, although physicians' underestimation of the benefits of exercise, health professionals' lack of knowledge about exercise training, and the absence of exercise advocates similar to pharmaceutical representatives may contribute. Absence of a conclusive, appropriately powered clinical trial may also contribute to underutilization, and some women may not want to participate in programs in which men predominate.¹⁵ Physician referral to cardiac rehabilitation will probably increase when referral to such programs becomes a core measure of hospital performance.⁵ Including an automatic referral to cardiac rehabilitation in standardized order sets for appropriate cardiac patients is among the best ways to increase referral rates.

THE FUTURE OF CARDIAC REHABILITATION

Use of cardiac rehabilitation should increase markedly if Medicare adopts referral to cardiac rehabilitation as a core performance measure for the management of patients with coronary disease and after cardiac surgery, as proposed.⁵ Furthermore, the ability of cardiac rehabilitation to reduce cardiac mortality and possibly recurrent cardiac events will probably be a component of any efforts to

control medical care costs by accountable care organizations.¹⁵ On the other hand, although data supporting the benefits of cardiac rehabilitation are highly regarded,³ they lack the support of large, appropriately powered clinical trials. Meta-analyses have the problem of positive paper publication bias and other issues, and many of the trials evaluated in available meta-analyses include studies that predate the present aggressive medical and interventional therapy for cardiac disease. Consequently, payers may limit reimbursement for cardiac rehabilitation in the future to control costs, although this outcome seems unlikely given Medicare's present evaluation of these data. Cost containment efforts could also result in the wider use of exercise-based cardiac rehabilitation and risk reduction programs to improve endothelial function and to manage angina pectoris and stable CAD before proceeding to more costly interventions such as PTCA and CABG. Such a change seems impossible in the present fee-for-service paradigm but is possible given the available comparisons of medical versus invasive strategies for the management of stable coronary disease, the physiology of the exercise-training response, and evidence that exercise training decreases cardiovascular events more than PTCA does in selected patients with angina pectoris.⁸

ACKNOWLEDGMENT

The author thanks the staff of the Hartford Hospital Cardiac Rehabilitation Program, Hartford, Conn., for the years of education they have provided to the author, as well as Lucie Bohannon, MS, PT, and Meg Flaherty, RN, for advice on the practical aspects of rehabilitation.

INTEGRATIVE CARDIOLOGY: OVERVIEW

Definition

Integrative cardiology recognizes the central role of nutrition and lifestyle for prevention and treatment of heart disease, combined with diverse, scientifically validated modalities of healing—all within the framework of guideline-based conventional cardiology care. Most importantly, integrative cardiology is not an alternative system for heart health but instead emphasizes a comprehensive approach that is inclusive of all useful healing modalities.

Integrative medicine should be distinguished from *complementary and alternative medicine* (CAM)—a term narrower in scope with variable scientific underpinning. CAM typically refers to healing modalities generally not part of conventional medicine, including but not limited to the use of supplements and herbs, massage, acupuncture, and mind-body approaches such as meditation, biofeedback, healing touch, and Reiki. *Integrative medicine* operates within the context of conventional medicine but selectively incorporates the most useful and scientifically valid of CAM approaches to achieve the best possible outcomes. In addition to prevention and treatment of physical disease states, the goals of an integrative medicine approach encompass spiritual and emotional well-being.

Rationale

Current approaches to cardiovascular care emphasize expert application of pharmacologic and procedural-based therapies. Even though enormous gains have been realized in modern cardiac care, some important gaps remain. For example, despite a wealth of evidence detailing the potency of nutrition as a therapeutic tool in cardiology, relatively little attention is directed to diet in most medical encounters (see Chapter 46). Similarly, research has confirmed the potent influence of mind-body interactions on heart health, yet the role of emotions is not typically emphasized in conventional care (see Chapter 86).

Cardiologists, like most physicians, receive relatively little formal training in certain areas, including nutrition, scientific assessment of supplements, and mind-body interactions. An integrative cardiology approach holds that health is optimized by the application of all useful healing modalities. Incorporation of an integrative approach to cardiology can enhance the efficacy of conventional medical interventions for prevention and treatment of cardiovascular disease—with the added benefit of reduced health care costs because of the emphasis on low-cost nutrition and lifestyle interventions.

Use

In the United States, an estimated 15 million individuals use some form of complementary and alternative therapy at an annual cost of almost \$30 billion.¹ Patient expenditure for CAM services in the United States is comparable to out-of-pocket patient expenses for conventional medical services and prescription drugs. Of note, health care professionals are more likely to use complementary and alternative therapies than the general public is (76% versus 63%, $P < 0.001$).²

The use of CAM treatments is particularly widespread among cardiology patients. A survey of the cardiology outpatient practice of a tertiary care center showed that 82% of cardiology patients used complementary and alternative therapies.³ Among these patients, 44% used CAM for the treatment of cardiac symptoms. The most frequently used CAM modalities were dietary supplements (75%), chiropractic (32%), massage (19%), and relaxation techniques (13%).³ The CAM therapies most commonly used specifically for the treatment of cardiac symptoms were related to mind-body interactions and included relaxation techniques, stress management, meditation, and guided imagery.

Of note, only 14% of patients who use CAM therapies discussed their choice with a physician.³ Patients often cite low expectation for physician knowledge of CAM and fear of ridicule as the reasons for not disclosing their use of CAM to physicians.

ELEMENTS OF AN INTEGRATIVE APPROACH IN CARDIOLOGY

Extended Face-to-Face Time with the Physician

One of the primary motivations for patients to seek integrative care is a desire for extended face-to-face time with their practitioner.⁴ Clinicians who provide longer visits are often viewed as more empathetic—a perspective with therapeutic implications. There is evidence that patients' perception of their physician's level of empathy is related to medical outcome, independent of disease variables.⁵

Patient Preference Sensitive

Another frequent driver for those seeking integrative care is the perceived enhanced sensitivity of integrative practitioners to patients' personal preferences and philosophy regarding their health care.⁴ Many patients seeking integrative medicine practitioners do so because they wish to minimize their use of prescription medication—or at least delay the need for prescription medication until nutrition and lifestyle measures have been maximized and shown to be inadequate. Patients' reluctance to take prescription medicine is reflected in data showing that as many as 50% of patients stop taking statin therapy within the first year of treatment.⁶

Nutrition Emphasis

An integrative approach emphasizes the role of nutrition in both prevention and treatment. Although nutrition is included in all guidelines for cardiovascular care, conventional cardiology practice does not consistently emphasize nutritional recommendations. Moreover, a recent study revealed that physician time spent in counseling patients regarding nutrition is declining—especially for diabetic patients.⁷ Current Accreditation Council for Graduate Medical Education guidelines, which consist of 32 pages of specific criteria for accreditation of cardiovascular training programs, include no requirement that nutrition be incorporated in the curriculum.⁸ Lack of adequate attention to nutrition results in lost opportunities for preservation of heart health, especially given data supporting a greater than 70% reduction in cardiovascular events by adoption of a Mediterranean-style diet.⁹

In addition to the clear therapeutic benefits of optimal nutrition, emphasizing the role of nutrition facilitates patient empowerment and engagement.

Exercise

Exercise is a component of almost all recommendations in cardiology but plays a more central role in an integrative cardiology approach. Focused attention on exercise is well justified in light of data demonstrating benefit from physical activity on symptoms and prognosis of almost every cardiac disorder ranging from hypertension and dyslipidemia to ischemic heart disease and congestive heart failure. For this reason, exercise, together with nutrition and stress management, forms the foundation of integrative cardiology—to which appropriate medication and procedures are added.

Mind-Heart Interactions

The existence of a strong connection between mind and heart health is intuitive but not consistently addressed in conventional cardiology encounters. Nevertheless, the nature of the mind-heart interaction has been well elucidated and includes hormonal input mediated through the central and autonomic nervous systems. A classic manifestation of the mind-heart interaction is takotsubo cardiomyopathy, a severe, acute-onset cardiomyopathy that is often triggered by an emotional stress response (see Chapter 65).

The integrative practitioner uses a wide range of options for stress management. In addition to the psychological resources commonly used in conventional medicine, including behavioral therapy and

antidepressant and anxiolytic medication, a wide variety of approaches may be considered in an integrative framework. Additional modalities for stress management include meditation, breathing exercises, biofeedback, massage, yoga, tai chi, and “energy” therapies such as healing touch and Reiki.

Healing Touch and Reiki

Healing touch and Reiki require special explanation because they are probably less familiar to most cardiologists. These modalities are based on the assumption of an “energy field” surrounding the body that can be manipulated by light touch and hand motions over the body focused on presumed energy centers. Some of the largest health care institutions in the United States have used such strategies as aids for stress reduction during recovering from cardiac surgery.

Acupuncture

Acupuncture has been shown to be effective in modulating sympathetic input to vascular beds in both experimental and clinical studies. Clinical studies of acupuncture have shown potential for use as an adjunct in the treatment of hypertension, palpitations, and congestive heart failure. Moreover, acupuncture can be an effective modality for reduction of emotional stress, an exacerbating factor in all cardiovascular disorders.

Supplements

In a survey of more than 1000 cardiology outpatients, 75% reported the use of some form of supplement or herbal products.³ The most common over-the-counter products include multivitamins (53%), fish oil (45%), vitamin C (36%), vitamin E (29%), fiber (27%), folic acid (18%), coenzyme Q₁₀ (CoQ₁₀) (12%), and garlic (12%).³ Many of these products are taken at the patient's own direction or on the recommendation of nonphysician health care providers. Some products that were initially prescribed predominantly by alternative health providers, such as fish oil and plant stanols, have been well studied and are now often recommended in conventional cardiology practice.

Cardiologists may not be aware of the vast and growing body of science surrounding the use of supplements. If for no other reason, knowledge of supplements is important so that clinicians can identify potential adverse reactions, as well as appreciate possible interactions with prescription medication. In selected cases, clinicians may choose to consider prescribing a supplement or herbal product, either as adjunctive treatment of patients receiving prescription medication or as an option for patients unable to tolerate prescription medication because of adverse reactions.

Fortunately, several excellent resources are available to help clinicians learn about the science of supplements, including those offered by the National Institutes of Health (NIH) Office of Dietary Supplements (<http://ods.od.nih.gov>), NIH National Center for Complementary and Alternative Medicine (<http://nccam.nih.gov>), and a service of the U.S. National Library of Medicine, MedlinePlus (http://www.nlm.nih.gov/medlineplus/druginfo/herb_All.html). Independent private groups that provide detailed scientific assessments of supplements include the Natural Medicines Database (<http://naturaldatabase.therapeuticresearch.com>) and the Natural Standard (<http://www.naturalstandard.com>). These Internet-based resources are extensively referenced to help guide clinical evaluation of the pharmacologic properties of supplements.

Apart from questions about the potential for clinical benefit from supplements, there is legitimate concern regarding the consistency of supplement content and absence of contamination. According to the U.S. Dietary Supplement Health and Education Act, the manufacturer is responsible for the accuracy of all information on the product label. Supplement manufacturers are required to follow Dietary Supplement Current Good Manufacturing Practices for quality control and to submit a list of adverse events to the U.S. Food and Drug Administration (<http://www.fda.gov/food/dietarysupplements>).

As an added assessment tool, certain supplements have been analyzed and certified by independent nonprofit groups that evaluate

TABLE 48-1 Most Useful Integrative Strategies for Prevention of Coronary Disease

Nutrition	Mediterranean diet led to a 72% reduction in cardiac events ⁹ ; healthiest diet linked to a 35% reduction in cardiovascular mortality ¹⁰
Exercise	Walking 30 min 5 days/wk reduces risk for coronary heart disease by 14% ¹¹
Meditation	Twice-daily meditation reduced cardiovascular events by 48% ¹²
Comprehensive lifestyle intervention	The combination of a low-fat, plant-based diet, exercise, and stress management led 74% of patients with angina to become asymptomatic ¹³
Red yeast rice	Red yeast rice resulted in a >20% reduction in LDL-C and was often tolerated in patients with previous statin-related myalgias ¹⁴

manufacturing procedures and product strength and purity, including the U.S. Pharmacopeial Convention (<http://www.usp.org>) and the National Sanitation Foundation (<http://www.nsf.org>). Another source of information for clinicians wishing to evaluate the quality of individual brands of supplements is Consumer Lab (<http://www.ConsumerLab.com>), an independent group that performs laboratory analyses on a variety of brands of common supplements and reports on dosage and purity.

PREVENTION OF CORONARY ARTERY DISEASE (Table 48-1)

Nutrition

Nutrition is the cornerstone of an integrative approach for both prevention and treatment of cardiovascular disease (see Chapter 46). A whole-diet approach is preferred over attention to individual nutrients. One of the best studied dietary approaches in cardiology is the Mediterranean-style diet—a relatively simple diet plan that includes increased intake of vegetables and fruit, preference for whole grains over refined, reduced red meat and increased fish consumption, and predominant use of olive and canola oil. The Mediterranean diet has been shown in the Lyon Diet Heart Study, a secondary prevention trial, to reduce risk for a cardiovascular event by 72% in comparison to controls.⁹ Adherence to a Mediterranean-style diet has been tested in diverse settings, including the United States, where the NIH-AARP study showed a reduction in both cardiovascular and cancer mortality rates in an observational study.¹⁵

Nutritional choices are associated with substantial mortality benefit in those already being treated with optimal medical therapy. In an analysis of more than 31,000 patients from two secondary prevention trials, those with the healthiest diet had a 35% lower cardiovascular mortality rate than did individuals consuming the least healthy diet. Even in the subset of patients being treated with combination medical therapy, including aspirin, beta blockers, and a statin, a healthier diet was associated with a 23% reduction in cardiovascular events.¹⁰

The Dietary Approaches to Stop Hypertension (DASH) diet, although initially conceived as an adjunct for treatment of hypertension (see Chapters 43 and 44), is similar to the Mediterranean diet with the exception of no specific recommendation for the preferred type of vegetable oil. In an observational study of more than 88,000 participants in the Nurses' Health Study, those with the strongest adherence to a DASH diet had an adjusted 24% reduction in coronary events and an 18% lower risk for stroke than did those with low adherence.¹⁶

A very consistent finding in nutritional studies is the strong cardiovascular benefit of high intake of vegetables and fruit. Dark green leafy vegetables, including spinach and kale, are especially cardioprotective, probably in part because of their high folate

concentration.¹⁷ Interestingly, the folic acid in supplements has not been demonstrated to reduce cardiovascular risk. The reason for this discordance is unclear but may be related to the fact that supplements are typically in the form of folic acid whereas food contains reduced forms of folate. For the folic acid found in supplements to be bioactive, it must first be metabolized by a process that can become overloaded when high doses of supplements are consumed, thereby resulting in a buildup of potentially harmful circulating free folic acid.¹⁸

Exercise

The role of exercise in the prevention and treatment of cardiovascular disease cannot be overemphasized (see Chapter 47). Most cardiovascular risk factors are improved through a combination of aerobic exercise, resistance training, and stretching. A dose-response relationship between exercise and cardiovascular benefit has been established, with a 14% reduction in risk for coronary heart disease noted with as little as 30 minutes of walking daily.¹¹ Interestingly, blood pressure reduction was found to be even greater when exercise was divided into three 10-minute walks versus a single 30-minute session daily.¹⁹ Nontraditional forms of exercise have also shown remarkable cardiovascular benefit, including tai chi, an ancient Chinese martial art form characterized by gentle, flowing movements often experienced as calming and meditative.²⁰

Mind-Heart Interactions

A clear association has been observed between emotional state and heart health (see Chapter 86). Identification of an increased tendency toward hostility was associated with a doubling of risk for ischemic heart disease over a 10-year period.²¹ A moderate or high level of perceived stress before myocardial infarction was associated with a 42% increase in 2-year mortality risk.²² Stress can induce ischemia by triggering both epicardial and microvascular vasoconstriction. In addition, stress leads to autonomic dysregulation and an outpouring of circulating catecholamines with potentially serious consequences, including takotsubo cardiomyopathy, or stress-related heart failure. The range of reported antecedent stressors to this potentially fatal condition is broad, including the death of a parent, a surprise birthday party, fear of a medical procedure, and public speaking.

Emotional factors identified early in life can predict those more likely to suffer cardiac events much later. Increased anxiety by 20 years of age was an independent predictor of future cardiac events, with more than a twofold increased risk for myocardial infarction over a 37-year follow-up.²³

Conversely, individuals with the most optimistic outlook appear to have some degree of cardioprotection when compared with their more pessimistic peers, with a 22% reduction in cardiac events over a 10-year follow-up.²⁴

Meditation

The potency of mind-body interventions is exemplified by a study of 201 patients following myocardial infarction, in whom a regular practice of meditation combined with optimal medical therapy resulted in a 48% reduction in major cardiovascular events in comparison to those treated with medical therapy alone.¹² Blood pressure was significantly reduced in the meditation group, a finding common to many mind-body intervention studies, including biofeedback, breathing exercises, and tai chi.

Multifaceted Lifestyle Intervention

The benefits of a comprehensive lifestyle intervention program, including nutritional changes (plant-based diet with 10% of calories from fat), exercise, and stress management, have been demonstrated in a study of 1152 individuals with coronary disease from 22 locations enrolled in the Multisite Cardiac Lifestyle Intervention Program. At 12 weeks into the program, 74% of those with angina at baseline were

asymptomatic. Among the remainder with persistent angina, 9% improved from limiting to mild angina.¹³

Supplements for Dyslipidemia

Supplement use is common in the treatment of dyslipidemia (see Chapters 41 and 42). Supplements may be used by patients who refuse prescription statins because of fear of adverse reactions, as well as by those with a history of statin intolerance. The frequency of adverse reactions to prescription statins, particularly muscle-related symptoms, is not commonly recognized but appears to be as high as 10% of all statin users.²⁵

Supplements with established efficacy in the treatment of dyslipidemia include psyllium, niacin, stanols/sterols, red yeast rice, and fish oil.

Psyllium

Psyllium is rich in soluble fiber, a component known to reduce absorption of cholesterol from the gastrointestinal tract. Psyllium at a dose of 10 g/day can reduce low-density lipoprotein cholesterol (LDL-C) by 7%.²⁶

Stanols/Sterols

Plant sterols and their derivatives stanols reduce absorption of cholesterol from the gastrointestinal tract. Stanols and sterols are available in pill form and in functional foods, including margarine. Two grams of stanols/sterols per day reduces LDL-C by approximately 10%.²⁶

Niacin

Niacin improves all major classes of lipids, including lowering of LDL-C, reduction of triglycerides, lowering of lipoprotein(a), and raising of high-density lipoprotein cholesterol (HDL-C) levels. Niacin is available as an over-the-counter product or by prescription. Effective over-the-counter forms include immediate-release crystalline niacin and a sustained- or timed-release variety.

"No-flush" or "flush-free" forms of niacin (inositol hexaniacinate) are inactive forms of niacin that are poorly metabolized into active free niacin and therefore have minimal efficacy in lowering lipid concentrations. Niacinamide and nicotinamide are often confused with niacin but have no lipid-lowering properties.

Strategies to reduce the transient hot flashes associated with prescription and over-the-counter niacin include taking niacin together with applesauce or premedication with aspirin or other nonsteroidal anti-inflammatories. Aspirin at a dose of 325 mg/day is more effective in reducing flushing than 80 mg/day is.²⁷

Red Yeast Rice

Red yeast rice is derived by fermentation of rice by the yeast *Monascus purpureus*, which yields a series of cholesterol-lowering monacolins. The monacolin in highest concentration in red yeast rice is monacolin K, also known as lovastatin. The degree of LDL lowering observed with the typical dosages of red yeast rice (1200 to 2400 mg/day) is disproportionately high given the relatively small amount of lovastatin (typically 5 to 10 mg), probably because of the contribution of other cholesterol-lowering constituents in red yeast rice.¹⁴

Brands of red yeast rice differ in both potency and purity. The concentration of total monacolins and monacolin K can vary severalfold between manufacturers. A small number of brands have been found to contain citrinin, a nephrotoxin.²⁸ Chemical analysis of various red yeast rice formulations, including assessment of monacolin concentration and testing for citrinin, is available through the independent group Consumer Labs (<http://www.Consumerlabs.com>). Clinical studies of a variety of red yeast rice preparations have demonstrated between 20% and 30% reductions in LDL-C. Red yeast rice has been studied in patients who have not been able to tolerate prescription statins, most often because of muscle-related complaints. Small studies have shown that as many as 86% of individuals previously intolerant of prescription statins were able to take red yeast rice without adverse reactions.¹⁴

Outcomes data for red yeast rice have been derived from a study of 4870 patients following myocardial infarction. In this 5-year study, red yeast rice resulted in a significant reduction in cardiovascular events, in addition to a 33% reduction in total mortality, relative to placebo.²⁹

Red yeast rice might be considered a therapeutic option for individuals with dyslipidemia who refuse or are intolerant of prescription statins. Because red yeast rice is a form of a statin, patients should be advised of precautions common to all statins and be monitored by a health care professional.

Fish Oil

Fish oil is the most commonly prescribed form of omega-3 fatty acid. Certain plant sources, including flaxseed, flaxseed oil, walnuts, and canola oil, are also rich in the omega-3 alpha-linolenic acid. These plant sources are less potent, however, because they require conversion into the more biologically active forms found naturally in fish oil, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Such conversion is extremely inefficient in humans, with only approximately 5% of alpha-linolenic acid converted into EPA and less than 1% into DHA.³⁰

The primary indication for prescribing fish oil is for the treatment of severe hypertriglyceridemia (see Chapter 45). For the treatment of triglycerides, fish oil has a linear dose-response relationship, with reductions of 30% or greater typical in patients with severe hypertriglyceridemia treated with 4 g/day of combined EPA and DHA.³¹

Fish oil has also been used for both primary and secondary prevention of cardiovascular disease, although these indications are controversial. A meta-analysis of 20 studies of omega-3 fatty acids (17 involving supplements only) that included 68,680 patients showed no overall benefit in reducing all-cause mortality, sudden death, cardiac death, or myocardial infarction.³² Similar results were noted in a previous meta-analysis of 20,485 patients.³³

The negative studies of fish oil are surprising in that early trials of fish oil supplementation, mostly targeted at secondary prevention, have shown promising benefit. Studies published over the past 5 years, however, have failed to demonstrate convincing benefit.³² The reason for the apparent diminution in benefit in more recent studies is unclear but could be related to improvements in background therapy, as well as increased omega-3 intake in the general population, including the control groups in fish oil trials.

Fish oil is available by prescription or as a supplement. In dosing fish oil in supplement form, care must be taken to evaluate not only the total amount of fish oil in each pill but also the EPA and DHA content listed on the nutrition label. The concentration of these active ingredients varies widely by brand, and a supplement of 1000 mg of fish oil could potentially contain only 1/3 EPA and DHA, thus requiring three pills daily if a total of 1000 mg of combined EPA and DHA is prescribed.

Other Supplements Used in Patients at Risk for Coronary Disease

Coenzyme Q₁₀

CoQ₁₀ is a component of the mitochondrial respiratory electron transport system needed to produce adenosine triphosphate (ATP). Statins reduce the production of mevalonate, an intermediary for both cholesterol production and the synthesis of CoQ₁₀. The reduced circulating levels of CoQ₁₀ observed in patients treated with statins has been postulated to be one of the mechanisms underlying statin-related myalgia.³⁴ Low blood levels of CoQ₁₀ are expected after statin therapy because approximately 58% of serum CoQ₁₀ is carried on LDL-C.³⁴ Although blood levels of CoQ₁₀ are reduced with statin therapy, tissue levels are not consistently altered, thus further confounding assessment of a causal relationship with myalgia.

Three randomized, placebo-controlled trials have been conducted to evaluate the impact of CoQ₁₀ in patients with statin-related myalgia. The CoQ₁₀ studies included from 32 to 76 patients, and CoQ₁₀ dosages ranged from 100 to 200 mg/day. Two studies showed no improvement

Supplements for Dyslipidemia with Minimal or No Efficacy

Policosanols

Although initial studies from one center reported significant improvement in dyslipidemia, similar results have not been replicated in later studies of policosanols of either sugar cane or beeswax origin.¹

Guggulipids

Guggul gum, or guggulipid, is an antagonist of the nuclear hormone receptors involved in bile acid and cholesterol metabolism. A study of 127 subjects using doses ranging from 50 mg to 6 g/day resulted in a reduction in LDL-C of 2%.¹

Garlic

Garlic has been shown in animal studies to reduce cholesterol absorption and inhibit cholesterol synthesis. Nevertheless, a meta-analysis of 13 trials that included 1056 individuals failed to show significant cholesterol lowering with garlic supplementation.²

Supplement Interactions with Warfarin

Clinicians caring for patients who require warfarin should be alerted to commonly used supplements that could cause serious interactions. Some commonly used supplements that can potentiate the risk for bleeding when used with warfarin include dong quai (used for osteoporosis and menstrual symptoms) and glucosamine hydrochloride (used for arthritis). Supplements that can inhibit the action of warfarin include American ginseng (taken for resistance to environmental stress) and St. John's wort (taken for depression).¹ A more comprehensive list of supplements that interact with warfarin and other medication can be found at www.naturaldatabase.com.

Reference

1. Natural Medicines Comprehensive Database. (<http://naturaldatabase.therapeuticresearch.com>).

in muscle-related symptoms.^{35,36} One study of 32 patients showed improvement in myalgia with CoQ₁₀, 100 mg/day.³⁷ No significant adverse reactions have been identified with CoQ₁₀. Because of the small sample sizes of the studies performed to date, definitive assessment of the role of CoQ₁₀ remains uncertain.

Vitamin D

Vitamin D regulates gene expression in a wide range of tissues related to cardiovascular health, including vascular smooth muscle cells, cardiac muscle cells, renin synthesis in the kidneys, and insulin secretion in the pancreas.³⁸ A low circulating level of vitamin D (25-hydroxyvitamin D <15 ng/mL) was associated with a 2.1-fold increase in the incidence of cardiac events in hypertensive patients studied in the Framingham Offspring Study.³⁹ Vitamin D intervention studies have yielded inconsistent results, with a review of eight randomized trials showing a small but insignificant reduction in cardiovascular risk (pooled risk, 0.90).⁴⁰

Vitamin D deficiency has also been studied as a potential contributor to statin intolerance. Statin-treated patients with myalgia were found to have a lower level of vitamin D than those without muscle symptoms, 29 versus 34 ng/mL ($P < 0.0001$). Vitamin D replacement to a mean level of 48 ng/mL resulted in resolution of myalgia in 92% (35/38 patients).⁴¹

Multivitamin

The Physicians' Health Study II evaluated the use of daily multivitamin intake for reduction of cardiovascular events in 14,641 men in a randomized, placebo-controlled trial. No cardiovascular benefit was observed after a mean treatment duration of 11 years.⁴² However, a small, but statistically significant reduction in the incidence of total cancers was noted.⁴³

Antioxidants

A plausible rationale exists to support a role for antioxidants in prevention of coronary artery disease (see Chapters 41 and 45). Oxidation of LDL increases its propensity for incorporation into atherosclerotic plaque. The potential role of antioxidants is consistent with the finding that vegetables and fruit with high antioxidant concentrations have been shown to be cardioprotective.⁴⁴ However, results from clinical trials of antioxidants taken in supplement form have been inconsistent, with most recent studies showing negative results.

Vitamin E

Although initial studies with vitamin E were promising, follow-up studies failed to demonstrate benefit for primary prevention in either men or women.^{45,46} Potential for harm has also been observed in some studies.⁴⁴

Vitamin E is a complex fat-soluble molecule that exists in eight different forms: four tocopherols and four tocotrienols. Alpha-tocopherol has been the most widely studied, and it is conceivable that different formulations of vitamin E, each with unique pharmacologic properties, would yield greater benefit. For example, alpha-tocopherol reduces the absorption of gamma-tocopherol, a potentially more effective antioxidant.⁴⁴

In addition, most vitamin E studies have used a synthetic form of alpha-tocopherol, a compound that increases vitamin E levels about half as much as the natural preparation does and is metabolized three to four times faster.⁴⁷ Therefore the form of vitamin E needs to be considered carefully when evaluating the results of clinical studies. Future trials involving different forms of natural vitamin E will be needed to more fully explore the possibility of a cardioprotective role for vitamin E.

Vitamin C

Vitamin C is a ubiquitous, highly potent, water-soluble antioxidant. Nevertheless, in pill form, typically at doses of 500 mg/day, few data support a reduction in cardiovascular events.⁴⁴⁻⁴⁶

Beta-Carotene

Carotenoids are antioxidants found in hundreds of natural pigments. Foods rich in carotenoids, such as carrots, spinach, and tomatoes, are associated with cardioprotection. Nonetheless, clinical trials involving beta-carotene supplements have largely been negative, with some evidence suggesting increased risk for angina, as well as lung cancer in smokers.⁴⁴

Folic Acid

Folic acid lowers the level of circulating homocysteine, a marker of increased risk for coronary heart disease and stroke. Therefore folic acid, often paired with vitamins B₆ and B₁₂, has been an appealing candidate for prevention of cardiovascular disease. Unfortunately, despite a 19% reduction in plasma homocysteine, folic acid supplementation has failed to demonstrate cardiovascular protection in secondary prevention trials.⁴⁸ Reasons for this counterintuitive finding are unclear, but possibilities include the fact that homocysteine could be a marker rather than a target for disease, as well as the possibility of folic acid causing an off-target adverse action offsetting the benefit of homocysteine reduction. A potential for risk from high-dose folic acid supplementation has been raised with the finding of an associated increased incidence of cancer.⁴⁹

In summary, the evidence clearly supports cardiovascular benefit from antioxidant-rich foods, but not from antioxidants in supplement form. There is an inherent difficulty in attempting to duplicate the protective properties of foods by reducing them to pill form. Identifying the ideal chemical form of antioxidant, proper dosage, and combination of nutrients needed to replicate the natural benefits of whole food has remained a challenge.

Chelation

Chelation therapy has been proposed as a method of treating coronary disease, with suggested mechanisms including sequestration of calcium from atherosclerotic plaque and reduction of oxidative stress leading to improved vascular function. In the Trial to Assess Chelation Therapy sponsored by the National Heart, Lung and Blood Institute and the National Center for Complementary and Alternative Medicine, 1708 patients with a history of myocardial infarction were randomly assigned to receive 40 infusions of a chelation solution with ethylenediaminetetraacetic acid or a placebo infusion, with a second randomization to an oral vitamin and mineral regimen or placebo. The findings demonstrated an 18% improvement in the primary endpoint of cardiac events ($P = 0.035$).⁵⁰ Subgroup analysis showed diabetic individuals to have particular benefit, with a 41% reduction in cardiac events ($P < 0.001$).⁵¹ The investigators cautioned that confirmatory evidence is needed before chelation can be adopted into clinical practice.

HYPERTENSION (Table 48-2; see Chapters 43 and 44)

Nutrition

DASH Diet

The DASH diet, which emphasizes increased consumption of vegetables, fruit, and low-fat dairy and low intake of saturated fat, resulted in a drop in systolic blood pressure of approximately 10 mm Hg and a reduction in diastolic blood pressure of 5 mm Hg in hypertensive patients versus controls. Of interest, a somewhat greater blood pressure-lowering effect was observed when the original DASH diet was modified by replacing carbohydrates with monounsaturated fat, similar to a Mediterranean-style diet.⁵²

Mind-Heart Interactions

Biofeedback

Slow breathing has been shown to increase parasympathetic activity and reduce sympathetic activation. Use of a device-guided

TABLE 48-2 Most Useful Integrative Strategies for Hypertension

Nutrition	The DASH diet led to a drop in blood pressure of 10 mm Hg systolic and 5 mm Hg diastolic ⁵²
Biofeedback	A program of slow-breathing exercises reduced blood pressure by 3.7 mm Hg systolic and 2.5 mm Hg diastolic ⁵³
CoQ ₁₀	CoQ ₁₀ at a dose of 100-120 mg/day resulted in a drop in blood pressure of 11 mm Hg systolic and 7 mm Hg diastolic ⁵⁴
Garlic	Garlic at dose of 600-900 mg/day reduced blood pressure by 8 mm Hg systolic and 7 mm Hg diastolic ⁵⁵

biofeedback program of slow breathing has been studied as a possible nonpharmacologic method of lowering blood pressure. In a meta-analysis of eight studies totaling 494 patients, a mean drop in blood pressure of 3.7 mm Hg systolic and 2.5 mm Hg diastolic was noted ($P = 0.002$). Large variations, however, were found between studies, with three trials showing no benefit.⁵³

Supplements

Omega-3 Fatty Acids

High doses of omega-3 polyunsaturated fatty acids, generally greater than 3 g/day, have been shown to result in modest but significant lowering of blood pressure. The degree of blood pressure reduction with omega-3 supplementation typically ranges between 2 and 6 mm Hg systolic and 2 and 4 mm Hg diastolic. DHA appears to be more effective than EPA in lowering blood pressure, although studies are inconsistent. Omega-3 fatty acids have a wide range of biologic properties that could contribute to blood pressure lowering, including stimulation of endothelial nitric oxide and reduced secretion of aldosterone.⁵⁶

Cocoa

The flavanols contained in cocoa are effective in stimulating the release of nitric oxide, the mechanism probably responsible for the associated reduction in blood pressure and improvement in endothelial function. A Cochrane review that included a meta-analysis of 20 studies totaling 856 patients concluded that intake of 4 to 105 g of cocoa products per day reduces blood pressure by 3 mm Hg systolic and 2 mm Hg diastolic in comparison to controls ($P < 0.01$).⁵⁷

Psyllium

Psyllium supplementation can aid in weight management and has been speculated to be beneficial for blood pressure reduction through improvement in endothelial dysfunction. In a 6-month study of 141 hypertensive overweight patients, psyllium powder resulted in a drop in blood pressure of 5 mm Hg systolic and 2 mm Hg diastolic after 6 months ($P < 0.001$). A decrease in body mass index of 1.0 kg/m² relative to the control group was noted ($P < 0.001$). The dose of psyllium studied was 3.5 g taken three times daily before meals.⁵⁸

Garlic

Garlic contains allicin, a compound that inhibits angiotensin II and induces vasodilation and blood pressure reduction. A meta-analysis of garlic supplementation in hypertensive patients found a reduction in blood pressure of 8 mm Hg systolic and 7 mm Hg diastolic. The daily dose of garlic was 600 to 900 mg.⁵⁵

Magnesium

The link between magnesium and hypertension has been studied extensively. An inverse relationship exists between serum magnesium and blood pressure, and low dietary magnesium intake is associated with hypertension. Patients who received supplemental magnesium at a dose of 600 mg/day showed a reduction of 4 mm Hg systolic and 2 mm Hg diastolic in comparison to controls.⁵⁹

Coenzyme Q₁₀

CoQ₁₀ is a potent antioxidant that has been postulated to have a direct action on vascular endothelium in reducing vascular resistance. In a recent Cochrane meta-analysis of three randomized placebo-controlled studies with a total of 96 patients, CoQ₁₀ was effective in lowering blood pressure in hypertensive individuals by 11 mm Hg systolic and 7 mm Hg diastolic in comparison to placebo. CoQ₁₀ doses ranged from 100 to 120 mg/day.⁵⁴

Acupuncture

Acupuncture was studied in 160 hypertensive patients randomly assigned to 22 treatments over a 6-week period that lasted 30 minutes each and consisted of active or sham acupuncture. The needling points of the active treatment group corresponded to a pattern established by traditional Chinese practitioners. Sham acupuncture used the same number of needles, but the insertion points were placed outside the traditional locations. At the completion of treatment, blood pressure dropped in the active acupuncture group by 6 mm Hg systolic and 4 mm Hg diastolic in comparison to sham controls ($P < 0.001$). By 6 weeks after completion of the acupuncture sessions, blood pressure returned to baseline levels.⁶⁰

CONGESTIVE HEART FAILURE (Table 48-3; see Chapters 22 to 25)

Nutrition

Healthy nutritional patterns are beneficial for prevention of congestive heart failure. In a study of 31,546 individuals, those with the most desirable nutritional intake (i.e., more vegetables and fruit, more fish relative to meat, less fried food) had a 28% lower risk for the development of congestive heart failure than did those consuming the least healthy diets.¹⁰ For those with established congestive heart failure, depletion of protein, as well as micronutrients, including vitamin C, vitamin D, magnesium, and zinc, has been described. There is evidence that nutritional replacement of these deficiencies may be beneficial.⁶¹

Mind-Heart Interactions

Meditation

Activation of the autonomic nervous underlies congestive heart failure and is generally considered to be involuntary. More recently, it has become evident that conscious maneuvers, including breathing exercises and meditation, can influence autonomic discharge and cardiac function.⁶² In the SEARCH (Support, Education, and Research in Chronic Heart Failure) study, an 8-week program of mindfulness-based meditation in 208 patients with New York Heart Association (NYHA) class II heart failure and a mean ejection fraction of 26% led to reduced anxiety and depression with continued improvement in heart failure symptoms that persisted for up to 1 year. "Our patients reported that mindfulness was helpful in dealing with acute dyspnea by reducing anxiety and catastrophic or pessimistic thinking, and promoting relaxation."⁶³ Six- to 12-week trials of biofeedback and tai chi in patients with congestive heart failure have also demonstrated improved exercise tolerance as measured by 6-minute walk distances.⁶²

TABLE 48-3 Most Useful Integrative Strategies for Congestive Heart Failure

Nutrition	Healthiest diet associated with a 28% lower risk for the development of congestive heart failure ¹⁰
Meditation	An 8-wk program of meditation led to improved congestive heart failure symptoms at 1 year ⁶³
CoQ ₁₀	A 3.7% increase in ejection fraction with CoQ ₁₀ , ≈100 mg/day, when the baseline ejection fraction was ≥30% ⁶⁴

Supplements

Coenzyme Q₁₀

Plasma CoQ₁₀ levels are an independent predictor of mortality in patients with congestive heart failure.⁶⁵ In a meta-analysis of 13 studies totaling 395 patients with congestive heart failure and systolic dysfunction, CoQ₁₀ supplementation resulted in a significant increase in the ejection fraction of 3.7% with a nonsignificant trend toward improvement in NYHA functional class. Trial duration was short (range, 2 to 28 weeks), and the CoQ₁₀ dose in 8 of the 13 trials was 100 mg or lower. The improvement in systolic function was greatest in those with a baseline ejection fraction of 30% or greater.⁶⁴

Hawthorn

Hawthorn extract is a popular herbal medicine proposed as an adjunctive treatment to conventional therapy for congestive heart failure. Pharmacologic actions include a positive inotropic effect and increased coronary blood flow. A 2008 Cochrane review of 14 trials concluded that hawthorn is associated with significant improvement in exercise tolerance and symptomatic relief.⁶⁶ Hawthorn doses varied widely between 160 and 1800 mg/day. A recent randomized trial of hawthorn in 2681 patients with NYHA class II or III congestive heart failure and a left ventricular ejection fraction reduced to 35% or less showed no benefit in the time to first cardiac event.⁶⁷

D-Ribose

D-Ribose is a pentose monosaccharide that stimulates purine synthesis and is integral to the production of ATP in the heart. A short-term trial of D-ribose, 5 g three times daily, in patients with ischemic heart disease and grade II to III congestive heart failure showed no improvement in systolic function but significant improvement in diastolic parameters and quality of life.⁶⁸

ARRHYTHMIAS (see Chapters 34 to 39)

Mind-Heart Interactions

There is strong evidence for a link between mental stress and sudden cardiac death. An increase in sudden cardiac death has been observed at the time of disasters, including earthquakes and missile attacks. Working individuals have a particularly high incidence of sudden death on Monday mornings.⁶⁹ Stress-induced sympathetic stimulation lowers the threshold for ventricular fibrillation and exacerbates the electrophysiologic effects of ischemia.⁶⁹

Yoga

In a crossover study of 52 patients with paroxysmal atrial fibrillation, a yoga program of 45-minute sessions three times per week for 3 months resulted in a 45% reduction in the number of episodes of atrial fibrillation in comparison to baseline ($P < 0.001$).⁷⁰

Acupuncture

The efficacy of acupuncture in preventing recurrence of atrial fibrillation was studied in 80 patients following restoration of sinus rhythm with electrical cardioversion. Patients were randomly assigned to receive acupuncture, sham acupuncture, or no further treatment and were compared with a reference group of patients taking amiodarone. The acupuncture regimen included 10 weekly treatments. During a 12-month follow-up, the recurrence rate of atrial fibrillation in the control group was 54%, which was reduced to 35% in the acupuncture group ($P = 0.075$), a recurrence rate similar to that of patients receiving amiodarone (27%).⁷¹

Supplements

Fish Oil

Omega-3 fatty acids have been evaluated for prevention of recurrent atrial fibrillation, but the results, although conflicting, have not been

encouraging. In a trial of 586 outpatients randomly assigned to receive approximately 850 mg combined EPA/DHA or placebo, no significant reduction in the recurrence rate of atrial fibrillation was noted in the treated group.⁷² Although early studies showed omega-3 to be beneficial for prevention of sudden cardiac death, a recent meta-analysis of 20 studies and 68,680 patients, including both primary and secondary prevention studies, demonstrated no reduction in the risk for sudden death.³²

For more on supplements, see ExpertConsult.com.

CARDIAC SURGERY

Massage

In a randomized trial of 152 patients, massage therapy significantly reduced pain and anxiety in the perioperative period after elective cardiac surgery when compared with a control group allocated to similar periods of undisturbed rest. Patients in the intervention group underwent 20 minutes of massage on postoperative days 3 or 4 and again on days 5 or 6.⁷³

Healing Touch

A randomized study of healing touch in 237 patients recovering from coronary artery bypass surgery demonstrated a 1-day shorter length of stay than in the subset of patients with elective surgery (6.2 days versus 7.2 days, $P = 0.01$), but no difference in length of stay in patients scheduled for surgery while hospitalized. A significant reduction in anxiety was also recorded in the healing touch group, but there was no decrease in the use of pain medication or in the incidence of atrial fibrillation. A total of three healing touch treatments were administered, including two 20- to 60-minute sessions on the day before and the day after surgery and a 60- to 90-minute session just before surgery.⁷⁴

Acupuncture

Acupuncture has also been used successfully in a randomized study of 90 cardiac surgery patients. A single preoperative acupuncture treatment reduced postoperative nausea by 74% early in the postoperative period in comparison to controls ($P = 0.01$).⁷⁵

CONCLUSION

As described in this chapter, a wide range of modalities can powerfully influence heart health—ranging from nutritional intervention to meditation.

An integrative approach to cardiology incorporates all useful healing modalities within the context of guideline-based care. This chapter has reviewed the latest research that adds further support to some of these modalities while negating the value of others. The value of maintaining both a critical eye and an open mind cannot be overemphasized.

By addressing an expanded number of factors influencing heart health, an integrative approach in cardiology has the potential to empower patients, reduce health care costs, and improve outcomes.

REFERENCES, 1055

The coronary circulation is unique in that the heart is responsible for generating the arterial pressure that is required to perfuse the systemic circulation and yet, at the same time, has its own perfusion impeded during the systolic portion of the cardiac cycle. Because myocardial contraction is closely connected to coronary flow and oxygen delivery, the balance between oxygen supply and demand is a critical determinant of the normal beat-to-beat function of the heart (Feigl, 1983 [classic reading]). When this relation is acutely disrupted by diseases affecting coronary blood flow the resulting imbalance can immediately precipitate a vicious cycle, whereby ischemia-induced contractile dysfunction precipitates hypotension and further myocardial ischemia. Thus knowledge of the regulation of coronary blood flow, determinants of myocardial oxygen consumption, and the relation between ischemia and contraction is essential for understanding the pathophysiologic basis and management of many cardiovascular disorders (Hoffman and Spaan, 1990 [classic reading]).

CONTROL OF CORONARY BLOOD FLOW

There are pronounced systolic and diastolic coronary flow variations throughout the cardiac cycle with coronary arterial inflow out of phase with venous outflow (Fig. 49-1). Systolic contraction increases tissue pressure, redistributes perfusion from the subendocardial to the subepicardial layers of the heart, and impedes coronary arterial inflow, which reaches a nadir. At the same time, systolic compression reduces the diameter of intramyocardial microcirculatory vessels (arterioles, capillaries, and venules) and increases coronary venous outflow, which peaks during systole. During diastole, coronary arterial inflow increases with a transmural gradient that favors perfusion to the subendocardial vessels. At this time, coronary venous outflow falls.

Determinants of Myocardial Oxygen Consumption

In contrast to most other vascular beds, myocardial oxygen extraction is near-maximal at rest, averaging 60% to 80% of arterial oxygen content.¹ The ability to increase oxygen extraction as a means to increase oxygen delivery is limited to circumstances associated with sympathetic activation and acute subendocardial ischemia. Nevertheless, coronary venous oxygen tension (PV_{O_2}) can only decrease from 25 mm Hg to approximately 15 mm Hg. Because of the high resting oxygen extraction, increases in myocardial oxygen consumption are primarily met by proportional increases in coronary flow and oxygen delivery (Fig. 49-2). In addition to coronary flow, oxygen delivery is directly determined by arterial oxygen content (Ca_{O_2}). This is equal to the product of hemoglobin concentration and arterial oxygen saturation plus a small amount of oxygen dissolved in plasma that is directly related to arterial oxygen tension (Pa_{O_2}). Thus, for any given flow level, anemia results in proportional reductions in oxygen delivery whereas hypoxia, due to the nonlinear oxygen dissociation curve, results in relatively small reductions in oxygen content until Pa_{O_2} falls to the steep portion of the oxygen dissociation curve (below 50 mm Hg).

The major determinants of myocardial oxygen consumption are heart rate, systolic pressure (or myocardial wall stress), and left ventricular (LV) contractility (see Figs. 21-21 and 54-2). A twofold increase in any of these individual determinants of oxygen consumption requires an approximately 50% increase in coronary flow. Experimentally, the systolic pressure volume area is proportional to myocardial work and linearly related to myocardial oxygen consumption. The basal myocardial oxygen requirements needed to maintain critical membrane function are low (approximately 15% of resting oxygen consumption), and the cost of electrical activation is trivial when mechanical contraction ceases during diastolic arrest (as with cardioplegia) and diminishes during ischemia.

FIGURE 49-1 Phasic coronary arterial inflow and venous outflow at rest and during adenosine vasodilation. Arterial inflow primarily occurs during diastole. During systole (dotted vertical lines), arterial inflow declines as venous outflow peaks, reflecting the compression of microcirculatory vessels during systole. After adenosine administration, the phasic variations in venous outflow are more pronounced. (Modified from Canty JM Jr, Brooks A: Phasic volumetric coronary venous outflow patterns in conscious dogs. *Am J Physiol* 258:H1457, 1990.)

Coronary Autoregulation

Regional coronary blood flow remains constant as coronary artery pressure is reduced below aortic pressure over a wide range when the determinants of myocardial oxygen consumption are kept constant. This phenomenon is termed *autoregulation* (Fig. 49-3). When pressure falls to the lower limit of autoregulation, coronary resistance arteries are maximally vasodilated to intrinsic stimuli, and flow becomes pressure-dependent, resulting in the onset of subendocardial ischemia. Resting coronary blood flow under normal hemodynamic conditions averages 0.7 to 1.0 mL/min/g and can increase between four- and fivefold during vasodilation (Klocke, 1976 [classic reading]). The ability to increase flow above resting values in response to pharmacologic vasodilation is termed *coronary flow reserve*. Flow in the maximally vasodilated heart is dependent on coronary arterial pressure. Maximum perfusion and coronary flow reserve are reduced when the diastolic time available for subendocardial perfusion is decreased (tachycardia) or the compressive determinants of diastolic perfusion (preload) are increased. Coronary reserve also is diminished by anything that increases resting flow, including increases in the hemodynamic determinants of oxygen consumption (systolic pressure, heart rate, and contractility) and reductions in arterial oxygen supply (anemia and hypoxia). Thus circumstances can develop that precipitate subendocardial ischemia in the presence of normal coronary arteries (Hoffman and Spaan, 1990 [classic reading]). Although initial studies suggested that the lower pressure limit of autoregulation is 70 mm Hg, Canty and associates (Fig. 49-4) have shown that coronary flow can be autoregulated to mean coronary pressures as low as 40 mm Hg (diastolic pressures of 30 mm Hg) in conscious dogs in the basal state. These coronary pressure levels are similar to those recorded in humans without symptoms of ischemia, distal to chronic coronary occlusions, using pressure wire micromanometers. The lower autoregulatory pressure limit increases during tachycardia because of an increase in flow requirements, as well as a reduction in the time available for perfusion.

Figure 49-4 also illustrates important transmural variations in the lower autoregulatory pressure limit, which result in increased vulnerability of the subendocardium to ischemia. Subendocardial flow occurs primarily in diastole and begins to decrease below a mean coronary pressure of 40 mm Hg. By contrast, subepicardial flow occurs throughout the cardiac cycle and is maintained until coronary pressure falls below 25 mm Hg. This difference arises from increased oxygen consumption in the subendocardium, requiring a higher

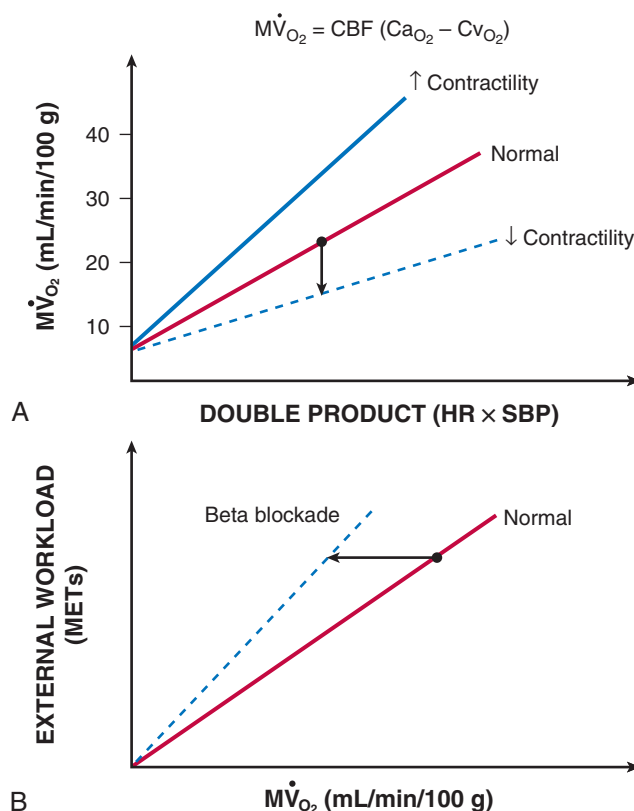

FIGURE 49-2 Fick equation and the relation between heart rate (HR)–systolic blood pressure (SBP) double product and myocardial oxygen consumption ($\dot{M}V_{O_2}$). **A**, Increases in $\dot{M}V_{O_2}$ are primarily met by increases in coronary flow and linearly related to the double product. A doubling of HR, SBP, or contractility each results in approximately 50% increases in myocardial oxygen consumption. **B**, Beta blockade allows the same external workload to be accomplished at a lower cardiac workload ($\dot{M}V_{O_2}$) by reducing the double product and myocardial contractility. Ca_{O_2} = coronary arterial oxygen content; CBF = coronary blood flow; Cv_{O_2} = coronary venous oxygen content.

resting flow level, as well as the more pronounced effects of systolic contraction on subendocardial vasodilator reserve. The transmural difference in the lower autoregulatory pressure limit results in vulnerability of the subendocardium to ischemia in the presence of a coronary stenosis. Although there is no pharmacologically recruitable flow reserve during ischemia in the normal coronary circulation, reductions in coronary flow below the lower limit of autoregulation can occur in the presence of pharmacologically recruitable coronary flow reserve under certain circumstances.²

Endothelium-Dependent Modulation of Coronary Tone. Epicardial conduit arteries do not contribute significantly to coronary vascular resistance, yet arterial diameter is modulated by a wide variety of paracrine factors that can be released from platelets, as well as circulating neurohormonal agonists, neural tone, and local control through vascular shear stress.¹ The most common factors related to cardiovascular disease are summarized in Table 49-1 (see also Fig. e49-1). The net effect of many of these agonists is critically dependent on whether a functional endothelium is present. Furchgott and Zawadzki (1980 [classic reading]) originally demonstrated that acetylcholine normally dilates arteries via an endothelium-dependent relaxing factor that was later identified to be nitric oxide (NO). This binds to guanylyl cyclase and increases cyclic guanosine monophosphate (cGMP), resulting in vascular smooth muscle relaxation. When the endothelium is removed, the dilation to acetylcholine is converted to vasoconstriction, reflecting the effect of muscarinic vascular smooth muscle contraction. Subsequent studies have demonstrated that coronary resistance arteries also exhibit endothelial modulation of diameter and that the response to physical forces such as shear stress, as well as paracrine mediators, vary with resistance vessel size.^{3,4} The major endothelium-dependent biochemical pathways

FIGURE e49-1 Endothelium-dependent control of vascular tone. In the normal coronary circulation, endothelium-dependent vasodilation occurs after increases in luminal flow or shear stress, as well as in response to agonists (e.g., released from platelets or cardiac nerves) that bind to receptors on the endothelial surface. These stimulate the production of NO, EDHF, or EETs (epoxyeicosatrienoic acid products), which diffuse into vascular smooth muscle and cause relaxation. Prostacyclin, or prostaglandin I_2 (PGI_2), is produced in the coronary endothelium of collateral vessels and causes tonic vasodilation. The endothelium also produces endothelin (ET), which activates protein kinase C in vascular smooth muscle to produce coronary constriction and competes with endothelium-derived relaxing factors. Impaired endothelium-dependent vasodilation can result from the lack of production of relaxing factors (e.g., disrupted endothelium) or by inactivation of nitric oxide in disease states associated with oxidative stress and superoxide anion production (e.g., NO and O_2^- combining to produce peroxynitrite). In these circumstances, the effect of autacoids on vascular tone can be converted to vasoconstriction because of their direct effects on vascular smooth muscle (not shown). AA = arachidonic acid; ACh = acetylcholine; Bk = bradykinin; 5-HT = 5-hydroxytryptamine [serotonin]; K_{Ca} = calcium-activated potassium channel; TGF β = transforming growth factor-beta-1; Thr = thrombin.

FIGURE 49-3 Autoregulatory relation under basal conditions and after metabolic stress (e.g., tachycardia). **Left**, The normal heart maintains coronary blood flow constant as regional coronary pressure is varied over a wide range when the global determinants of oxygen consumption are kept constant (red lines). Below the lower autoregulatory pressure limit (approximately 40 mm Hg), subendocardial vessels are maximally vasodilated and myocardial ischemia develops. During vasodilation (blue lines), flow increases four to five times above resting values at a normal arterial pressure. Coronary flow ceases at a pressure higher than right atrial pressure (P_{RA}), called zero flow pressure ($P_{f=0}$), which is the effective back pressure to flow in the absence of coronary collaterals. **Right**, After stress, tachycardia increases the compressive determinants of coronary resistance by decreasing the time available for diastolic perfusion and thus reduces maximum vasodilated flow. LV hypertrophy and microvascular disease also limit maximal blood flow per gram of myocardium. In addition, increases in myocardial oxygen demand or reductions in arterial oxygen content (e.g., from anemia or hypoxemia) increase resting flow. These changes reduce coronary flow reserve, the ratio between dilated and resting coronary flow, and cause ischemia to develop at higher coronary pressures. Hb = hemoglobin; HR = heart rate; SBP = systolic blood pressure.

FIGURE 49-4 Transmural variations in coronary autoregulation and myocardial metabolism. Increased vulnerability of the subendocardium (ENDO; red) versus subepicardium (EPI; gold) to ischemia reflects the fact that autoregulation is exhausted at a higher coronary pressure (40 versus 25 mm Hg). This is the result of increased resting flow and oxygen consumption in the subendocardium and an increased sensitivity to systolic compressive effects, because subendocardial flow only occurs during diastole. Subendocardial vessels become maximally vasodilated before those in the subepicardium as coronary artery pressure is reduced. These transmural differences can be increased further during tachycardia or during conditions with elevated preload, which reduce maximum subendocardial perfusion. (Modified from Canty JM Jr: Coronary pressure-function and steady-state pressure-flow relations during autoregulation in the unanesthetized dog. *Circ Res* 63:821, 1988.)

TABLE 49-1 Endothelium-Dependent and Net Direct Effects of Neural Stimulation, Autacoids, and Vasodilators on Coronary Tone in Isolated Conduit and Coronary Resistance Arteries

SUBSTANCE	ENDOTHELIUM-DEPENDENT	NORMAL RESPONSE	ATHEROSCLEROSIS
Acetylcholine			
Conduit	Nitric oxide	Net dilation	Constriction
Resistance	Nitric oxide, EDHF	Dilation	Attenuated dilation
Norepinephrine			
Conduit			
Alpha ₁		Constriction	Constriction
Beta ₁ and Beta ₂	Nitric oxide	Dilation	Attenuated dilation
Resistance			
Alpha ₁		Constriction	Constriction
Alpha ₂	Nitric oxide	No effect	Constriction
Beta ₂		Dilation	Dilation
Platelets			
Thrombin	Nitric oxide	Dilation	Constriction
Serotonin			
Conduit	Nitric oxide	Constriction	Constriction
Resistance	Nitric oxide	Dilation	Constriction
Adenosine diphosphate (ADP)	Nitric oxide	Dilation	Attenuated dilation
Thromboxane	Endothelin	Constriction	Constriction
Paracrine agonists			
Bradykinin	Nitric oxide, EDHF	Dilation	Attenuated dilation
Histamine	Nitric oxide	Dilation	Attenuated dilation
Substance P	Nitric oxide	Dilation	Attenuated dilation
Endothelin (ET)			
ET-1	Nitric oxide	Net constriction	Increased constriction
Vasodilators			
Adenosine		Dilation	Dilation
Regadenoson		Dilation	Dilation
Dipyridamole		Dilation	Dilation
Papaverine		Dilation	Dilation
Nitroglycerin		Dilation	Dilation
Calcium channel blockers		Dilation	Submaximal dilation

involved in regulating coronary epicardial and resistance artery diameter are as follows.

Nitric Oxide (Endothelium-Derived Relaxing Factor). NO is produced in endothelial cells by the enzymatic conversion of L-arginine to citrulline via type III NO synthase (NOS). Endothelial NO diffuses abluminally into vascular smooth muscle, where it binds to guanylyl cyclase, increasing cGMP production and causing relaxation through a reduction in intracellular calcium. NO-mediated vasodilation is enhanced by cyclic or pulsatile changes in coronary shear stress. Chronic upregulation of NOS occurs in response to episodic increases in coronary flow, such as during exercise training, which also potentiates the relaxation to various endothelium-dependent vasodilators. NO-mediated vasodilation is impaired in many disease states and in patients with one or more risk factors for coronary artery disease (CAD). This occurs via inactivation of NO by superoxide anion generated in response to oxidative stress. Such inactivation is the hallmark of impaired NO-mediated vasodilation in atherosclerosis, hypertension, and diabetes.

Endothelium-Dependent Hyperpolarizing Factor. Endothelium-dependent hyperpolarization is an additional endothelium-dependent

mechanism for selected agonists (e.g., bradykinin), as well as shear stress-induced vasodilation, in the human coronary microcirculation. Endothelium-dependent hyperpolarizing factor (EDHF), produced by the endothelium, hyperpolarizes vascular smooth muscle and dilates arteries by opening calcium-activated potassium channels (K_{Ca}). The exact biochemical species of EDHF is still unclear, but prominent candidates are endothelium-derived hydrogen peroxide and epoxyeicosatrienoic acid, a metabolite of arachidonic acid metabolism produced by the cytochrome P-450 epoxygenase pathway.⁵

Prostacyclin. Metabolism of arachidonic acid via cyclooxygenase also can produce prostacyclin, which is a coronary vasodilator when administered exogenously. Although some evidence indicates that prostacyclin contributes to tonic coronary vasodilation, inhibitors of cyclooxygenase fail to alter flow during ischemia distal to an acute stenosis or limit oxygen consumption in response to increases in metabolism. This suggests that it is overcome by other compensatory vasodilator pathways.² In contrast with the coronary resistance vasculature, vasodilator prostaglandins are very important determinants of coronary collateral vessel resistance, and inhibiting cyclooxygenase reduces collateral perfusion in dogs.⁶

Endothelin. The endothelins—ET-1, ET-2, and ET-3—are peptide endothelium-dependent constricting factors. ET-1 is a potent constrictor derived from the enzymatic cleavage of a larger precursor molecule (pre-pro-endothelin) via endothelin-converting enzyme. In contrast with the rapid vascular smooth muscle relaxation and recovery characteristic of endothelium-derived vasodilators (NO, EDHF, and prostacyclin), the constriction to endothelin is prolonged. Changes in endothelin levels are largely mediated through transcriptional control and produce longer-term changes in coronary vasomotor tone. The effects of endothelin are mediated by binding to both ETA and ETB receptors. ETA-mediated constriction is caused by the activation of protein kinase C in vascular smooth muscle. ETB-mediated constriction is less pronounced and counterbalanced by ETB-mediated endothelium-dependent NO production and vasodilation. Endothelin is only marginally involved in regulating coronary blood flow in the normal heart but can modulate vascular tone when interstitial and circulating concentrations increase in pathophysiologic states such as heart failure.

Determinants of Coronary Vascular Resistance

The resistance to coronary blood flow can be divided into three major components, as summarized in **Figure 49-5** (Klocke, 1976 [classic reading]). Under normal circumstances, there is no measurable pressure drop in the epicardial arteries, indicating negligible conduit resistance (R_1). With the development of hemodynamically significant epicardial artery narrowing (more than 50% diameter reduction), the fixed conduit artery resistance begins to contribute an increasing component to total coronary resistance and, when severely narrowed (more than 90%), may reduce resting flow.

The second component of coronary resistance (R_2) is dynamic and arises primarily from microcirculatory resistance arteries and arterioles. This is distributed throughout the myocardium across a broad range of microcirculatory resistance vessel sizes (20 to 400 μm in diameter) and changes in response to physical forces (intraluminal pressure and shear stress), as well as the metabolic needs of the tissue. Normally, little resistance is contributed by coronary venules and capillaries, and their resistance remains fairly constant during changes in vasomotor tone. Even in the maximally vasodilated heart, capillary resistance accounts for no more than 20% of the microvascular resistance.⁴ Thus a twofold increase in capillary density would increase maximal myocardial perfusion by only approximately 10%. Minimal coronary vascular resistance of the microcirculation is primarily determined by the size and density of arterial resistance vessels and results in substantial coronary flow reserve in the normal heart.

Extravascular Compressive Resistance

The third component, extravascular compressive resistance (R_3), varies with time throughout the cardiac cycle and is related to cardiac contraction and systolic pressure development within the left ventricle. In heart failure, compressive effects from elevated ventricular diastolic pressure also impede perfusion by passive compression of microcirculatory vessels from elevated extravascular tissue pressure during diastole. Increases in preload effectively raise the normal back pressure to coronary flow above coronary venous pressure levels (Hoffman and Spaan, 1990 [classic

reading]). Compressive effects are most prominent in the subendocardium and are discussed in greater detail further on.

During systole, cardiac contraction raises extravascular tissue pressure to values equal to LV pressure at the subendocardium. This declines to values near pleural pressure at the subepicardium. The increased effective back pressure during systole produces a time-varying reduction in the driving pressure for coronary flow that impedes perfusion to the subendocardium. Although this paradigm can explain variations in systolic coronary inflow, it is not able to account for the increase in coronary venous systolic outflow. To explain both impaired inflow and accelerated venous outflow, some investigators have proposed the concept of the intramyocardial pump (Hoffman and Spaan, 1990 [classic reading]). In this model, microcirculatory vessels are compressed during systole and produce a capacitive discharge of blood that accelerates flow from the microcirculation to the coronary venous system (**Fig. 49-6**). At the same time, the upstream capacitive discharge impedes systolic coronary arterial inflow. Although this explains the phasic variations in coronary arterial inflow and venous outflow, as well as its transmural distribution in systole, vascular capacitance cannot explain compressive effects related to elevated tissue pressure during diastole. Thus intramyocardial capacitance, compressive changes in effective coronary backpressure, increases in systolic coronary resistance, and a time-varying driving pressure all contribute to the compressive determinants of phasic systolic coronary blood flow.

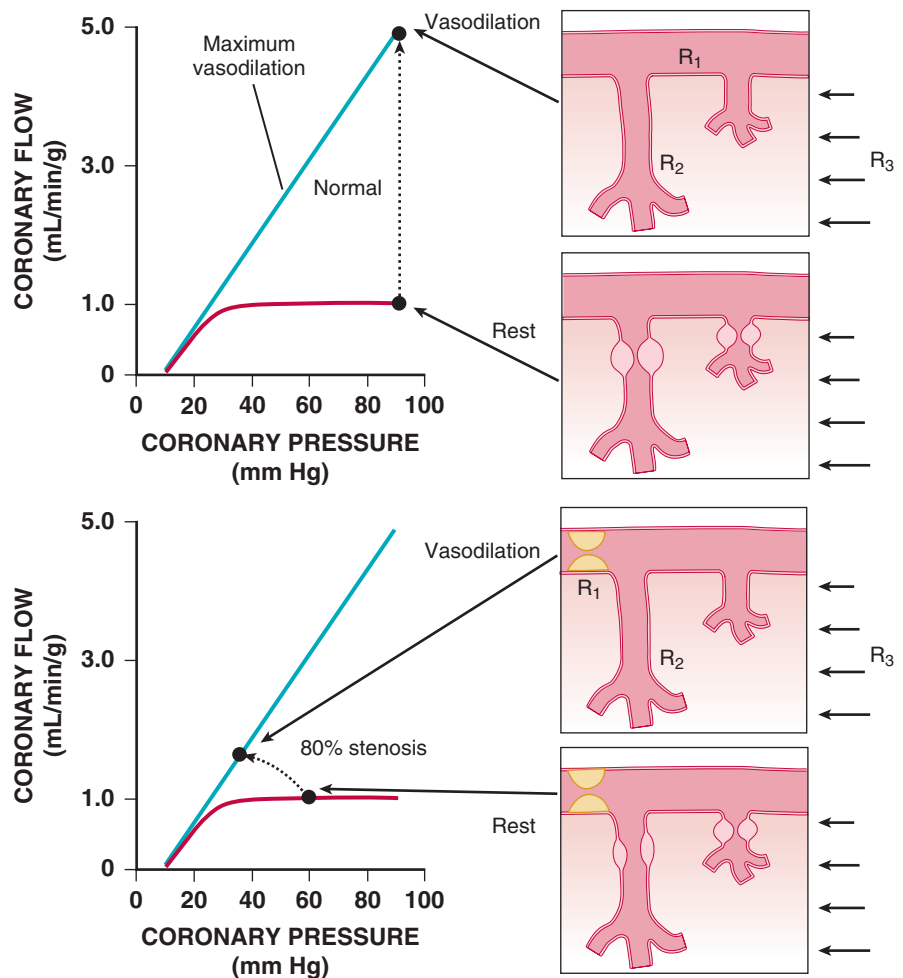

FIGURE 49-5 Schematic of components of coronary vascular resistance with and without a coronary stenosis. R_1 is epicardial conduit artery resistance, which normally is insignificant; R_2 is resistance secondary to metabolic and autoregulatory adjustments in flow and occurs in arterioles and small arteries; and R_3 is the time-varying compressive resistance that is higher in subendocardial than subepicardial layers. In the normal heart (**upper panel**), $R_2 > R_3 \gg R_1$. The development of a proximal stenosis or pharmacologic vasodilation reduces arteriolar resistance (R_2). In the presence of a severe epicardial stenosis (**lower panel**), $R_1 > R_3 > R_2$.

FIGURE 49-6 Effects of extravascular tissue pressure on transmural perfusion. Compressive effects during diastole (**A**) are related to tissue pressures that decrease from the subendocardium (Endo) to subepicardium (Epi). At diastolic LV pressures greater than 20 mm Hg, preload determines the effective back pressure to coronary diastolic perfusion. During systole (**B**), cardiac contraction increases intramyocardial tissue pressure surrounding compliant arterioles and venules. This produces a concealed arterial “backflow” that reduces systolic epicardial artery inflow, as depicted in Figure 49-1. Compression of venules accelerates venous outflow. (Modified from Hoffman JJ, Spaan JA: Pressure-flow relations in the coronary circulation. *Physiol Rev* 70:331, 1990.)

Transmural Variations in Minimum Coronary Resistance (R_2) and Diastolic Driving Pressure

The subendocardial vulnerability to compressive determinants of vascular resistance is partially compensated for by a reduced minimal resistance resulting from an increased arteriolar and capillary density. Because of this vascular gradient, subendocardial flow during maximal pharmacologic vasodilation of the nonbeating heart is greater than subepicardial perfusion. Coronary vascular resistance in the maximally vasodilated heart also is pressure-dependent, reflecting passive distention of arterial resistance vessels. Thus the instantaneous vasodilated value of coronary resistance obtained at a normal coronary distending pressure will be lower than that at a reduced pressure.

The precise determinants of the effective driving pressure for diastolic perfusion continue to be controversial. Most experimental studies demonstrate that the effective back pressure to flow in the heart is higher than right atrial pressure. This has been termed *zero flow pressure* ($P_{f=0}$) and its minimum value is approximately 10 mm Hg in the maximally vasodilated heart. This increases to values close to LV diastolic filling pressure when preload is elevated above 20 mm Hg. Elevated preload reduces coronary driving pressure and diminishes subendocardial perfusion. It is particularly important in determining flow when coronary pressure is reduced by a stenosis, as well as in the failing heart.

Structure and Function of the Coronary Microcirculation

The schematics in Figures 49-4 and 49-5 suggest a fairly localized site for the control of coronary vascular resistance that is useful for conceptualizing the major determinants of coronary vascular resistance.

In fact, individual coronary resistance arteries are a longitudinally distributed network and in vivo studies of the coronary microcirculation have demonstrated considerable spatial heterogeneity of specific resistance vessel control mechanisms^{3,4,6} (Fig. 49-7). Each resistance vessel needs to dilate in an orchestrated fashion to meet the needs of the downstream vascular bed, which is frequently removed from the site of metabolic control of coronary resistance. This can be accomplished independently of metabolic signals by sensing physical forces such as intraluminal flow (shear stress-mediated control) or intraluminal pressure changes (myogenic control). Epicardial arteries (more than 400 μ m in diameter) serve a conduit artery function, with diameter primarily regulated by shear stress, and contribute little pressure drop (less than 5%) over a wide range of coronary flow. Coronary arterial resistance vessels can be divided into small arteries (100 to 400 μ m), which regulate their tone in response to local shear stress and luminal pressure changes (myogenic response), and arterioles (<100 μ m), which are sensitive to changes in local tissue metabolism and directly control perfusion of the low-resistance coronary capillary bed (Fig. 49-8; see also Fig. e49-2).^{3,4} Capillary density of the myocardium averages 3500/mm² (resulting in an average intercapillary distance of 17 μ m), which is greater in the subendocardium than in the subepicardium.

Under resting conditions, most of the pressure drop in the microcirculation arises in resistance arteries between 50 and 200 μ m, with little pressure drop occurring across capillaries and venules at normal flow levels (Fig. e49-2A).⁴ After pharmacologic vasodilation with dipyridamole, resistance artery vasodilation attenuates the pre-capillary pressure drop in arterial resistance vessels. At the same time, there is an increased pressure drop and redistribution of resistance to venular vessels, in which smooth muscle relaxation is limited and the already low resistance is fairly fixed.

Considerable heterogeneity in microcirculatory vasodilation is evident during physiologic adjustments in flow. For example, as pressure is reduced during autoregulation, dilation is accomplished primarily by arterioles smaller than 100 μ m, whereas larger resistance arteries tend to constrict because of the reduction in perfusion pressure (Fig. e49-2B).⁴ By contrast, metabolic vasodilation results from a more uniform vasodilation of resistance vessels of all sizes (Fig. e49-2C).⁴ Similar inhomogeneity in resistance vessel dilation occurs in response to endothelium-dependent agonists as well as pharmacologic vasodilators.

A unique component of subendocardial coronary resistance vessels is the transmural penetrating arteries that course from the epicardium to the subendocardial plexus.² These vessels not only are less sensitive to metabolic signals but are also removed from the metabolic stimuli that develop when ischemia is confined to the subendocardium. As a result, local control by altered shear stress and myogenic relaxation to local pressure become very critical determinants of diameter in this “upstream” resistance segment. Even during maximal vasodilation, this segment creates an additional longitudinal component of coronary vascular resistance that must be traversed before the arteriolar microcirculation is reached. Because of this greater longitudinal pressure drop, the microcirculatory pressures in subendocardial coronary arterioles are lower than in the subepicardial arterioles.⁴

Intraluminal Physical Forces Regulating Coronary Resistance.

Because much of the coronary resistance vasculature can be upstream from the effects of metabolic mediators of control, local vascular control mechanisms are critically important in orchestrating adequate regional tissue perfusion to the distal microcirculation. The differential expression of mechanisms that is evident among different sizes and classes of coronary resistance vessels coincides with their function.

Myogenic Regulation. The myogenic response refers to the ability of vascular smooth muscle to oppose changes in coronary arterial diameter.³ Thus vessels relax when distending pressure is decreased and constrict when distending pressure is elevated (Fig. 49-9A). Myogenic tone is a property of vascular smooth muscle and occurs across a large size range of coronary resistance arteries in animals as well as in humans. Although the cellular mechanism is uncertain, it is

FIGURE e49-2 Microcirculatory pressure profile and local resistance changes to physiologic stimuli in subepicardial microvessels. **A**, Under resting conditions, most of the pressure drop to flow arises from small arteries and arterioles. After dipyridamole vasodilation, a redistribution of microcirculatory resistance is seen, with a greater pressure drop occurring across small arteries and postcapillary venules that do not alter their resistance. **B**, Heterogeneous arterial microvessel response during autoregulation. A reduction in pressure to 38 mm Hg elicited dilation in arterioles smaller than 100 μm , whereas larger arteries tended to constrict passively from the reduction in distending pressure. **C**, Homogeneous vasodilation of resistance arteries during increases in myocardial oxygen consumption. Dilation occurs in all microvascular resistance arteries, being greatest in vessels smaller than 100 μm . (**A**, Modified from Chilian WM, Layne SM, Klausner EC, et al: Redistribution of coronary microvascular resistance produced by dipyridamole. *Am J Physiol* 256:H383, 1989; **B**, modified from Kanatsuka H, Lamping KG, Eastham CL, et al: Heterogeneous changes in epimyocardial microvascular size during graded coronary stenosis. Evidence of the microvascular site for autoregulation. *Circ Res* 66:389, 1990; **C**, modified from Kanatsuka H, Lamping KG, Eastham CL, et al: Comparison of the effects of increased myocardial oxygen consumption and adenosine on the coronary microvascular resistance. *Circ Res* 65:1296, 1989.)

FIGURE 49-7 Transmural distribution of coronary resistance vessels—major vasodilatory and vasoconstrictor mechanisms in epicardial conduit arteries and different sites of the microcirculation. The epicardial conduit arteries arborize into subepicardial and subendocardial resistance arteries. Intramural penetrating resistance arteries are unique in that they are removed from subendocardial metabolic stimuli and theoretically are more dependent on regulating their tone in response to shear stress and luminal pressure as mechanisms to produce dilation in response to changes in metabolism of the distal subendocardial arteriolar plexus. See text for further discussion. AII = angiotensin II; ACh = acetylcholine; ET = endothelin; 5-HT = 5-hydroxytryptamine [serotonin]; K_{ATP} = ATP-dependent potassium channel; $NE\beta_1$ = norepinephrine beta₁ adrenergic; $NE\alpha_1$ = norepinephrine alpha₁ adrenergic; TXA_2 = thromboxane A₂. (Modified from Duncker DJ, Bache RJ: Regulation of coronary vasomotor tone under normal conditions and during acute myocardial hypoperfusion. *Pharmacol Ther* 86:87, 2000.)

FIGURE 49-8 Integrative regulation of coronary flow by ascending, metabolic, myogenic, and shear stress-induced mechanisms in response to metabolic activation. Small distal arterioles immediately before the capillaries are sensitive to tissue metabolites. Upstream intermediate arterioles are pressure-sensitive, with myogenic mechanisms predominating. Small resistance arteries are removed from the metabolic milieu and primarily adjust local tone in response to shear stress and flow. Capillary and venular resistances are small and primarily considered to be fixed. (Modified from Davis MJ, Hill MA, Kuo L: Local regulation of microvascular perfusion. In Tuma RF, Duran WN, Ley K (eds): *Handbook of Physiology: Microcirculation*. San Diego, Academic Press, 2008, p 161.)

dependent on vascular smooth muscle calcium entry, perhaps through stretch-activated L-type Ca^{2+} channels, eliciting cross-bridge activation. The resistance changes arising from the myogenic response tend to bring local coronary flow back to the original level. Myogenic regulation has been postulated to be one of the important mechanisms of the coronary autoregulatory response and, in vivo, appears to primarily occur in arterioles smaller than 100 μm (e.g., during autoregulation); (see Fig. e49-2B).

Flow-Mediated Resistance Artery Control. Coronary small arteries and arterioles also regulate their diameter in response to

changes in local shear stress (see Fig. 49-9B). Flow-induced dilation in isolated coronary arterioles is endothelium-dependent and mediated by NO, because it could be abolished with an L-arginine analogue. By contrast, isolated atrial vessels from patients undergoing cardiac surgery exhibit flow-mediated vasodilation that is mediated by EDHF.^{7,8} The disparity with animal studies may reflect age or species variability in the relative importance of EDHF versus NO in the coronary circulation. The mechanisms also appear to vary as a function of vessel size, with studies in pigs demonstrating that hyperpolarization regulates epicardial conduit arteries,⁹ and NO predominates in the resistance

FIGURE 49-9 Effects of physical forces on coronary diameter in isolated human coronary resistance arteries (nominal diameter, 100 μ m). **A**, As distending pressure is reduced from 100 mm Hg, progressive vasodilation occurs, consistent with myogenic regulation. Myogenic dilation reaches the maximum passive diameter of the vessel at 20 mm Hg. **B**, Flow-mediated vasodilation in cannulated human resistance arteries. As the pressure gradient across the isolated vessel is increased, intraluminal flow rises, causing progressive dilation that is abolished by removing the endothelium. Similar flow-mediated dilation occurs in most arterial vessels, including the coronary conduit arteries. (**A**, Modified from Miller FJ, Dellsperger KC, Guterman DD: Myogenic constriction of human coronary arterioles. *Am J Physiol* 273:H257, 1997; **B**, modified from Miura H, Wachtel RE, Liu Y, et al: Flow-induced dilation of human coronary arterioles: Important role of Ca^{2+} -activated K^+ channels. *Circulation* 103:1992, 2001.)

vasculature. Finally, EDHF may represent a compensatory pathway that normally is inhibited by NO and becomes upregulated in acquired disease states in which NO-mediated vasodilation is impaired.⁷ More recent studies have demonstrated that this factor appears to be hydrogen peroxide.¹⁰ Despite the variability in isolated vessels, blocking NOS with an L-arginine analogue in the coronary circulation of humans reduces vasodilation to pharmacologic endothelium-dependent agonists and attenuates flow increases during metabolic vasodilation. This demonstrates that NO-mediated vasodilation plays a role in determining physiologic vascular tone in some segments of the coronary resistance vasculature.

Metabolic Mediators of Coronary Resistance Vessel Control. Although increasing knowledge has emerged regarding the distribution of coronary microvascular resistance, there is still no consensus regarding specific mediators of metabolic vasodilation.¹¹ Coronary resistance in any segment of the microcirculation represents the integration of local physical factors (e.g., pressure and flow), vasodilator metabolites (e.g., adenosine, Po_2 , and pH), autacoids, and neural modulation. Each of these mechanisms contributes to net coronary vascular smooth muscle tone, which may ultimately be controlled by opening and closing vascular smooth muscle adenosine triphosphate (ATP)-sensitive K^+ (K_{ATP}) channels. There is considerable redundancy in the available local control mechanisms.² Because of this, blocking single mechanisms fails to alter coronary autoregulation or metabolic flow regulation at normal coronary pressures. This redundancy can, however, be unmasked by stressing the heart and evaluating flow regulation at reduced pressures distal to a coronary stenosis at rest or during exercise.² Some of the candidates proposed and their role in metabolic resistance control and ischemia-induced vasodilation are summarized here; for more extensive discussion, see the classic reference by Feigl (1983).

Adenosine. There has been a longstanding interest in the role of adenosine as a metabolic mediator of resistance artery control. It is released from cardiac myocytes when the rate of ATP hydrolysis exceeds its synthesis during ischemia. Its production and release also increase with myocardial metabolism. Adenosine has an extremely short half-life (less than 10 seconds) caused by its rapid inactivation by adenosine deaminase. It binds to A_2 receptors on vascular smooth muscle, increases cyclic adenosine monophosphate (cAMP), and opens K_{ATP} ⁶ and intermediate calcium-activated potassium channels.¹² Adenosine has a differential effect on coronary resistance arteries, primarily dilating vessels smaller than 100 μ m.⁴ Although adenosine has no direct effect on larger resistance arteries and conduit arteries, these dilate through endothelium-dependent vasodilation from the concomitant increases in local shear stress as arteriolar resistance falls.³ Despite the attractiveness of adenosine as a local metabolic control mechanism, there is now substantial in vivo experimental data

to demonstrate convincingly that it is not required for adjusting coronary flow to increases in metabolism or autoregulation.⁶ It may, however, contribute to vasodilation during hypoxia as well as during acute exercise-induced myocardial ischemia distal to a stenosis.²

ATP-Sensitive K^+ Channels. Coronary vascular smooth muscle K_{ATP} channels are tonically active, contributing to coronary vascular tone under resting conditions. Preventing K_{ATP} channel opening with glibenclamide causes constriction of arterioles smaller than 100 μ m, reduces coronary flow, and accentuates myocardial ischemia distal to a coronary stenosis by overcoming intrinsic vasodilator mechanisms.² The K_{ATP} channels can modulate both the coronary metabolic and autoregulatory responses. It is a potentially attractive mechanism, because many of the other candidates for metabolic flow regulation (e.g., adenosine, NO, β_2 -adrenoreceptors, prostacyclin) are ultimately affected by blocking this pathway. It is likely that K_{ATP} channel opening is a common effector rather than sensor of metabolic activity or of autoregulatory adjustments in flow. It is also possible that the reductions in coronary flow observed after blocking K_{ATP} channel vasodilation are pharmacologic, caused by vasoconstriction of the microcirculation that overcomes intrinsic vasodilator stimuli, as seen when other potent vasoconstrictors (e.g., endothelin or vasopressin) are administered at pharmacologic doses.

Oxygen Sensing. Although a potent coronary vasodilator stimulus, the role of local Po_2 in the regulation of arteriolar tone remains unresolved. Coronary flow increases in proportion to reductions in arterial oxygen content (reduced Po_2 or anemia) and there is a twofold increase in perfused capillary density in response to hypoxia. The underlying mechanism may involve the release of NO and ATP (which stimulates vascular endothelial P2 receptors to produce NO) from red blood cells, when intravascular Po_2 levels drop.¹ Studies demonstrating a direct effect of oxygen on metabolic or autoregulatory adjustments are lacking, however, and the vasodilator response to reduced arterial oxygen delivery may simply reflect the close coupling between myocardial metabolism and flow.

Acidosis. Arterial hypercapnia and acidosis (Pco_2) are potent stimuli that have been demonstrated to produce coronary vasodilation independent of hypoxia. Whereas their precise role in the local regulation of myocardial perfusion remains unclear,¹ it seems reasonable that some of the vasodilation occurring with increased myocardial metabolism could arise from increased myocardial CO_2 production and tissue acidosis in the setting of acute ischemia.

Neural Control of Coronary Conduit and Resistance Arteries

Sympathetic and vagal nerves innervate coronary conduit arteries and segments of the resistance vasculature. Neural stimulation

affects tone through mechanisms that alter vascular smooth muscle as well as by stimulating the release of NO from the endothelium. Diametrically opposite effects can occur in the presence of risk factors that impair endothelium-dependent vasodilation. Their actions in normal and pathophysiologic states are summarized in Table 49-1.

Cholinergic Innervation

Resistance arteries dilate to acetylcholine, resulting in increases in coronary flow. In conduit arteries, acetylcholine normally causes mild coronary vasodilation. This reflects the net action of a direct muscarinic constriction of vascular smooth muscle counterbalanced by an endothelium-dependent vasodilation caused by direct stimulation of NOS and an increased flow-mediated dilation from concomitant resistance vessel vasodilation. The response in humans with atherosclerosis or risk factors for CAD is distinctly different. The resistance vessel dilation to acetylcholine is attenuated and the reduction in flow-mediated NO production leads to net epicardial conduit artery vasoconstriction, which is particularly prominent in stenotic segments (Fig. 49-10A).

Sympathetic Innervation

Under basal conditions, there is no resting sympathetic tone in the heart and thus there is no effect of denervation on resting perfusion. During sympathetic activation, coronary tone is modulated by norepinephrine released from myocardial sympathetic nerves, as well as by circulating norepinephrine and epinephrine.¹³ In conduit arteries, sympathetic stimulation leads to α_1 constriction as well as beta-mediated vasodilation. The net effect is to dilate epicardial coronary arteries. This dilation is potentiated by concomitant flow-mediated vasodilation from metabolic vasodilation of coronary resistance vessels. When NO-mediated vasodilation is impaired, α_1 constriction predominates and can dynamically increase stenosis severity in asymmetrical lesions where the stenosis is compliant. This is one of the mechanisms by which ischemia can be provoked during cold pressor testing (Fig. 49-10B).

The effects of sympathetic activation on myocardial perfusion and coronary resistance vessel tone are complex and dependent on the net actions of beta₁-mediated increases in myocardial oxygen consumption (resulting from increases in the determinants of myocardial oxygen consumption), direct beta₂-mediated coronary vasodilation, and alpha₁-mediated coronary constriction. Under normal conditions, exercise-induced beta₂-adrenergic “feed-forward” dilation predominates, resulting in a higher flow relative to the level of myocardial oxygen consumption.⁶ This neural control mechanism produces transient vasodilation before the buildup of local metabolites during exercise and prevents the development of subendocardial ischemia during abrupt changes in demand. After nonselective beta blockade, sympathetic activation unmasks alpha₁-mediated coronary artery constriction. Although flow is mildly decreased, oxygen delivery is maintained by increased oxygen extraction and a reduction in

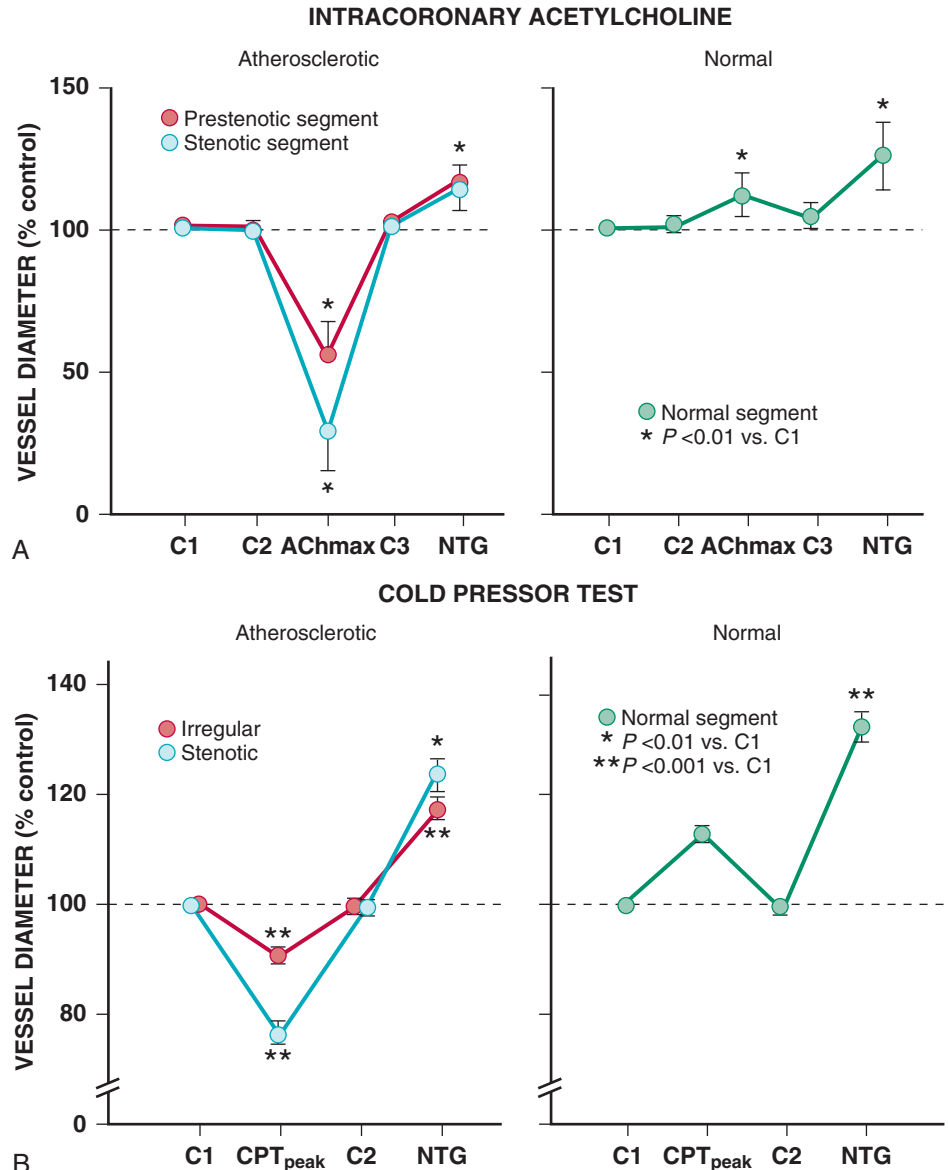

FIGURE 49-10 Differential conduit artery diameter responses in normal and atherosclerotic epicardial arteries. **A**, Acetylcholine. In normal arteries, acetylcholine elicits vasodilation but there is vasoconstriction in the atherosclerotic artery, which is particularly pronounced in the stenosis. **B**, Cold pressor testing. Activation of sympathetic tone normally leads to net epicardial dilation, but vasoconstriction in irregular and stenotic coronary segments occurs in patients with atherosclerosis. ACh = acetylcholine; C = control; CPT = cold pressor test [response]; NTG = nitroglycerin. (A, Modified from Ludmer PL, Selwyn AP, Shook TL, et al: Paradoxical vasoconstriction induced by acetylcholine in atherosclerotic coronary arteries. *N Engl J Med* 315:1046, 1986; B, modified from Nabel EG, Ganz P, Gordon JB, et al: Dilation of normal and constriction of atherosclerotic coronary arteries caused by the cold pressor test. *Circulation* 77:43, 1988.)

coronary venous PO_2 at similar levels of cardiac workload. Intense alpha₁-adrenergic constriction can overcome intrinsic stimuli for metabolic vasodilation to result in ischemia in the presence of pharmacologic vasodilator reserve.¹³ The role of pre- and postsynaptic alpha₂ responses is controversial. They appear to have a less significant role in controlling flow. This partly reflects the competing effects of presynaptic alpha₂ receptor stimulation, leading to reduced vasoconstriction by inhibiting norepinephrine release.

Paracrine Vasoactive Mediators and Coronary Vasospasm

There are a large number of paracrine factors that can affect coronary tone in normal and pathophysiologic states that are unrelated to normal coronary circulatory control. The most important of these are summarized in Table 49-1 and Figure 49-7 (see also Fig. e49-1).

Paracrine factors are released from epicardial artery thrombi after activation of the thrombotic cascade initiated by plaque rupture. They can modulate epicardial tone in regions near eccentric ulcerated plaques that are still responsive to stimuli that alter smooth muscle relaxation and constriction, leading to dynamic changes in the physiologic significance of a stenosis. Paracrine mediators also can have differential effects on downstream vessel vasomotion that are dependent on vessel size (conduit arteries versus resistance arteries) as well as on the presence of a functionally normal endothelium, because many also stimulate the release of NO and EDHF.

Serotonin released from activated platelets causes vasoconstriction in normal and atherosclerotic conduit arteries and can increase the functional severity of a dynamic coronary stenosis through superimposed vasospasm. By contrast, it dilates coronary arterioles and increases coronary flow through the endothelium-dependent release of NO. In atherosclerosis or circumstances in which NO production is impaired, the direct effects on smooth muscle predominate and the response of the microcirculation is converted to vasoconstriction. As a result, serotonin release generally exacerbates ischemia in CAD.

Thromboxane A₂ is a potent vasoconstrictor that is a product of endoperoxide metabolism and released during platelet aggregation. It produces vasoconstriction of conduit arteries as well as isolated coronary resistance vessels and can accentuate acute myocardial ischemia.

Adenosine diphosphate (ADP) is another platelet-derived vasodilator that relaxes coronary microvessels as well as conduit arteries. It is mediated by NO and abolished by removing the endothelium.

Thrombin normally leads to vasodilation in vitro that is endothelium-dependent and mediated by the release of prostacyclin as well as NO. In vivo, it also releases thromboxane A₂, leading to vasoconstriction in epicardial stenoses in which endothelium-dependent vasodilation is impaired. In the coronary resistance vasculature, it acts as an endothelium-dependent vasodilator and increases coronary flow.

Coronary Vasospasm

Coronary spasm results in transient functional occlusion of a coronary artery that is reversible with nitrate vasodilation. It most commonly occurs in the setting of a coronary stenosis, leading to dynamic stenosis behavior that can dissociate the effects on perfusion from anatomic stenosis severity (see Chapter 20). In CAD, endothelial disruption probably plays a role in focal vasospasm. In this setting, the normal vasodilation from autacoids and sympathetic stimulation is converted into a vasoconstrictor response because of the lack of competing endothelium-dependent vasodilation. Nevertheless, although impaired endothelium-dependent vasodilation is a permissive factor for vasospasm, it is not causal, and a trigger is required (e.g., thrombus formation or sympathetic activation).

The mechanisms responsible for variant angina with normal coronary arteries, or Prinzmetal angina, are less clear. Data from animal models have pointed to sensitization of intrinsic vasoconstrictor mechanisms.¹⁴ Coronary arteries demonstrate supersensitivity to vasoconstrictor agonists in vivo and in vitro as well as reduced vasodilator responses. Some studies have demonstrated that Rho, a guanosine triphosphate (GTP)-binding protein, can sensitize vascular smooth muscle to calcium by inhibiting myosin phosphatase activity through the effector protein Rho kinase.

Pharmacologic Vasodilation. The effects of pharmacologic vasodilators on coronary flow reflect direct actions on vascular smooth muscle as well as secondary adjustments in resistance artery tone. Flow-mediated dilation can amplify the vasodilator response, whereas autoregulatory adjustments can overcome vasodilation in a segment of the microcirculation and restore flow to normal. The potent resistance vessel vasodilators are specifically used in assessing coronary stenosis severity.¹⁵

Nitroglycerin. Nitroglycerin dilates epicardial conduit arteries and small coronary resistance arteries but does not increase coronary

blood flow in the normal heart.² The latter observation reflects the fact that transient arteriolar vasodilation is overcome by autoregulatory escape, which returns coronary resistance to control levels.^{3,4} Although nitroglycerin does not increase coronary blood flow in the normal heart, it can produce vasodilation of larger coronary resistance arteries that improves the distribution of perfusion to the subendocardium when flow-mediated NO-dependent vasodilation is impaired.² It also can improve subendocardial perfusion by reducing LV end-diastolic pressure through systemic venodilation in heart failure. Similarly, coronary collateral vessels dilate in response to nitroglycerin, and the reduction in collateral resistance can improve regional perfusion in some settings.⁶

Calcium Channel Blockers. All calcium channel blockers induce vascular smooth muscle relaxation and are to various degrees pharmacologic coronary vasodilators. In epicardial arteries, the vasodilator response is similar to nitroglycerin and is effective in preventing coronary vasospasm superimposed on a coronary stenosis as well as in normal arteries of patients with variant angina. They also submaximally vasodilate coronary resistance vessels. In this regard, dihydropyridine derivatives such as nifedipine are particularly potent and can sometimes precipitate subendocardial ischemia in the presence of a critical stenosis. This arises from a transmural redistribution of blood flow (coronary steal) as well as the tachycardia and hypotension that transiently occur with short half-life formulations of nifedipine.

Adenosine and A₂ Receptor Agonists. Adenosine dilates coronary arteries through activation of A₂ receptors on vascular smooth muscle and is independent of the endothelium in coronary arterioles isolated from humans with heart disease.¹² Experimentally, a differential sensitivity of the microcirculation to adenosine is observed, with the direct effects related to resistance vessel size and restricted primarily to vessels smaller than 100 μ m.^{3,4} Larger upstream resistance arteries dilate via a NO-dependent mechanism from the increase in shear stress. Thus, in states in which endothelium-dependent vasodilation is impaired, maximal coronary flow responses to intravenous or intracoronary adenosine may be reduced in the absence of a stenosis⁴ and can be increased by interventions that improve NO-mediated vasodilation, such as lowering low-density lipoprotein (LDL) levels. Single-dose adenosine A₂ receptor agonists (e.g., regadenoson) are now clinically available and are equally effective as adenosine. These agents circumvent the need for continuous infusions during myocardial perfusion imaging (see Chapter 16).¹⁵

Dipyridamole. Dipyridamole produces vasodilation by inhibiting the myocyte reuptake of adenosine released from cardiac myocytes. It therefore has actions and mechanisms similar to those of adenosine, with the exception that the vasodilation is more prolonged. It can be reversed via the administration of the nonspecific adenosine receptor blocker aminophylline.

Papaverine. Papaverine is a short-acting coronary vasodilator that was the first agent used for intracoronary vasodilation. It causes vascular smooth muscle relaxation by inhibiting phosphodiesterase and increasing cAMP. After bolus injection, it has a rapid onset of action but the vasodilation is more prolonged than after adenosine (approximately 2 minutes). Its actions are independent of the endothelium.

Right Coronary Artery Flow

Although the general concepts of coronary flow regulation developed for the left ventricle apply to the right ventricle, there are differences related to the extent of the right coronary artery supply to the right ventricular free wall. This has been studied in dogs, in which the right coronary artery is a nondominant vessel.¹⁶ In terms of coronary flow reserve, arterial pressure supplying the right coronary substantially exceeds right ventricular pressure, minimizing the compressive determinants of coronary reserve. Right ventricular oxygen consumption is lower than that in the left ventricle, and coronary venous oxygen saturations are higher than in the left coronary circulation. Because there is considerable oxygen extraction reserve, coronary flow decreases as pressure is reduced and oxygen delivery is maintained by increased extraction. These differences appear specific to the right ventricular free wall. In humans, where the right coronary artery is dominant (see Chapter 20) and supplies a large amount of the inferior left ventricle, factors affecting flow regulation to the LV myocardium are likely to predominate.

PHYSIOLOGIC ASSESSMENT OF CORONARY ARTERY STENOSES

The physiologic assessment of stenosis severity is a critical component of the management of patients with obstructive epicardial CAD (see Chapter 54).¹⁷ Epicardial artery stenoses arising from atherosclerosis increase coronary resistance and reduce maximal myocardial perfusion. Abnormalities in coronary microcirculatory control also can contribute to causing myocardial ischemia in many patients. Separating the role of a stenosis from coronary resistance vessels can be accomplished by simultaneously assessing coronary flow and distal coronary pressure using intracoronary transducers that are currently available for clinical care (see Chapter 55).^{18,19}

Stenosis Pressure-Flow Relation

The angiographically visible epicardial coronary arteries are normally able to accommodate large increases in coronary flow without producing any significant pressure drop and thus serve a conduit function to the coronary resistance vasculature. This changes dramatically in CAD, in which the epicardial artery resistance becomes dominant. This fixed component of resistance increases with stenosis severity and limits maximal myocardial perfusion.

As a starting point, it is helpful to consider the idealized relation among stenosis severity, pressure drop, and flow that has been validated in animals as well as in humans studied under circumstances in which diffuse atherosclerosis and risk factors that can impair microcirculatory resistance vessel control are minimized. Figure 49-11 summarizes the major determinants of stenosis energy losses. The relation between pressure drop across a stenosis and coronary flow for stenoses between 30% and 90% diameter reduction can be described using the Bernoulli principle. The total pressure drop across a stenosis is governed by three hydrodynamic factors—viscous losses, separation losses, and turbulence, although the last usually is a relatively minor component of pressure loss. The single most important determinant of stenosis resistance for any given level of flow is the minimum lesional cross-sectional area within the stenosis (Klocke, 1983 [classic reading]). Because resistance is inversely proportional to the square of the cross-sectional area, small dynamic changes in luminal area caused by thrombi or vasomotion in asymmetrical lesions (where vascular smooth muscle can relax or constrict in a portion of the stenosis) lead to major changes in the stenosis pressure-flow relation and reduce maximal perfusion during vasodilation. Separation losses determine the curvilinearity

or “steepness” of the stenosis pressure-flow relation and become increasingly important as stenosis severity and/or flow rate increases. Stenosis length and changes in cross-sectional area distal to the stenosis are relatively minor determinants of resistance for most coronary lesions.

Diffuse abluminal outward remodeling with thickening of the arterial wall is common in coronary atherosclerosis but does not alter the pressure-flow characteristics of the stenosis for a given intraluminal geometry. By contrast, diffuse inward remodeling effectively reduces minimal lesion area along the length of the vessel and can lead to underestimation of stenosis severity using relative diameter or area measurements (see Chapter 20) and at the same time contribute to a significant longitudinal pressure drop that also reduces maximum perfusion.¹⁷

Stenosis pressure drop and resistance increase exponentially as minimum lesional cross-sectional area decreases (Fig. 49-12A, B). This reflects the fact that the pressure drop becomes flow-dependent and varies with the square of the flow or flow velocity. As a result, the instantaneous stenosis resistance progressively increases during vasodilation. This becomes particularly important in determining the stenosis pressure-flow behavior for severely narrowed arteries and leads to a situation in which small reductions in luminal area result in large reductions in poststenotic coronary pressure that limit maximum coronary perfusion of the distal microcirculation.

Interrelation of Distal Coronary Pressure, Flow, and Stenosis Severity

Because maximum myocardial perfusion is ultimately determined by the coronary pressure distal to a stenosis, it is helpful to place the epicardial stenosis pressure-flow relation into the context of the coronary autoregulatory and vasodilated coronary pressure-flow relations, as also depicted in Figure 49-12. The effects of a stenosis on resting and vasodilated flow as a function of percentage diameter reduction, when diffuse intraluminal narrowing is absent and coronary microcirculatory resistance is normal, are summarized in Figure 49-12C. Because of coronary autoregulation, flow remains constant as stenosis severity increases. Thus imaging resting perfusion cannot identify hemodynamically significant stenoses (see Chapter 16). By contrast, the maximally vasodilated pressure-flow relation is much more sensitive to detect increases in stenosis severity. There is normally substantial coronary flow reserve and flow can increase approximately five times the resting flow values. As illustrated in Figure 49-12D, there is no significant pressure drop across a stenosis (ΔP) or stenosis-related alteration in maximal myocardial perfusion until stenosis severity exceeds a 50% diameter reduction (cross sectional area reduction of 75%). As stenosis severity exceeds 50%, the curvilinear coronary stenosis pressure-flow relation steepens and increases in stenosis resistance are accompanied by concomitant increases in ΔP across the stenosis (see Fig. 49-12A). This reduces distal coronary pressure, the major determinant of perfusion to the microcirculation, and maximum vasodilated flow (and coronary flow reserve) decreases. A critical stenosis, one in which subendocardial flow reserve is completely exhausted at rest, usually develops when stenosis severity exceeds 90%. Under these circumstances, pharmacologic vasodilation of subepicardial resistance vessels results in a reduction in distal coronary pressure that actually redistributes flow away from the subendocardium, leading to a “transmural steal” phenomenon.⁶

FIGURE 49-11 Fluid mechanics of a stenosis. The pressure drop across a stenosis can be predicted by the Bernoulli equation. It is inversely related to the minimum stenosis cross-sectional area and varies with the square of the flow rate as stenosis severity increases. A_n = area of the normal segment; A_s = area of the stenosis; f_1 = viscous coefficient; f_2 = separation coefficient; L = stenosis length; μ = viscosity of blood; ρ = density of blood; ΔP = pressure drop; \dot{Q} = flow.

Concept of Maximal Perfusion and Coronary Reserve

Gould originally proposed the concept of coronary reserve.¹⁷ With technological advances, it has become possible to characterize this in humans using invasive catheter-based measurements of intracoronary pressure and flow (see Chapter 55) (Fig. 49-13) as well as with noninvasive imaging of myocardial perfusion with positron emission tomography (PET), single photon emission tomography (SPECT), and, more recently, cardiac magnetic resonance (CMR) (see Chapters 16 and 17). With physiologically based approaches to quantify perfusion and coronary pressure, it also has become

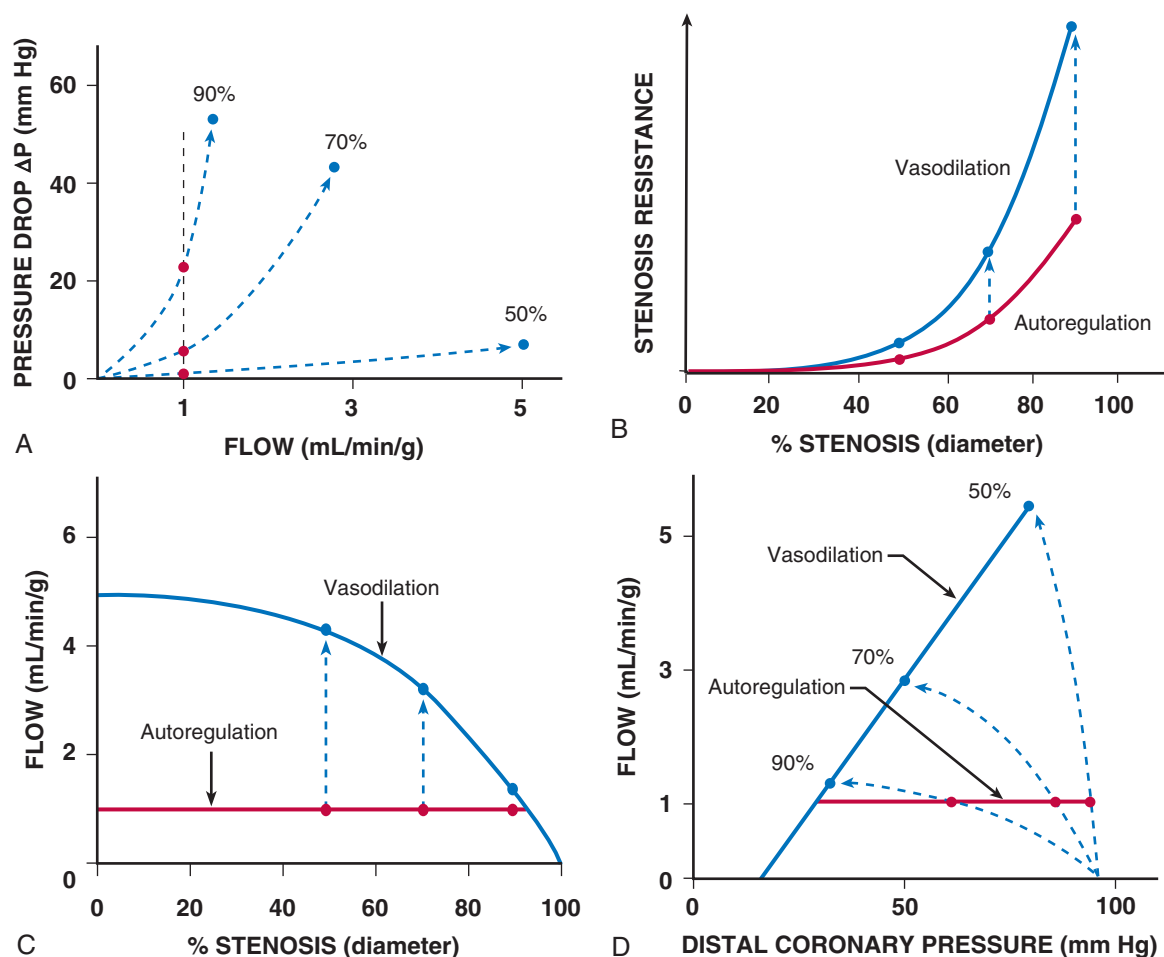

FIGURE 49-12 Interrelation of the epicardial artery stenosis pressure-flow relation (A), stenosis resistance at the autoregulated resting and maximally vasodilated flow (B), absolute coronary flow reserve (C), and the distal coronary pressure-flow relation (D). Red circles and lines depict resting flow and blue circles and lines maximal vasodilation for stenoses of 50%, 70%, and 90% diameter reduction. As shown in A, the stenosis pressure-flow relation becomes extremely nonlinear as stenosis severity increases. Thus the instantaneous resistance of the stenosis increases during vasodilation (B). As a result of the nonlinear stenosis pressure-flow behavior, very little pressure drop across a 50% stenosis is seen, and distal coronary pressure and vasodilated flow remain near normal. By contrast, a 90% stenosis critically impairs flow and, because of the steepness of the stenosis pressure-flow relation, causes a marked reduction in distal coronary pressure. See text for further discussion.

FIGURE 49-13 Coronary pressure and flow velocity tracings in a patient with an intermediate stenosis. After intracoronary adenosine administration, flow velocity transiently increases and mean distal coronary pressure (Pd) falls. Absolute coronary flow reserve (CFR) is the ratio of peak flow to resting flow. FFR is the ratio of Pd/Pao (distal coronary pressure divided by mean aortic pressure).

increasingly apparent that abnormalities in coronary microcirculatory control contribute to the functional significance of isolated epicardial artery stenoses in many patients with CAD, as well as leading to impaired coronary flow responses in the presence of normal coronary arteries. Because of these complexities, multiple complimentary approaches frequently are required to define limitations in myocardial perfusion that arise from stenosis severity versus abnormalities of the coronary microcirculation. The three major indices currently used to quantify coronary flow reserve are absolute, relative, and fractional flow reserve. These are compared in **Figure 49-14**, and the relative advantages and limitations of each are discussed next.

Absolute Flow Reserve. Initial approaches to assess functional stenosis severity focused on assessing the relative increase in flow after ischemic vasodilation (reactive hyperemic response after transient occlusion of the coronary artery) or pharmacologic vasodilation of the microcirculation with intracoronary papaverine, adenosine, or intravenous dipyridamole. Absolute flow reserve can be quantified using intracoronary Doppler velocity or thermodilution flow measurements, as well as by quantitative approaches to image absolute tissue perfusion based on PET and MRI. It is expressed as the ratio of maximally vasodilated flow to the corresponding resting flow value in a specific region of the heart and quantifies the ability of flow to increase above the resting value (see **Fig. 49-14A**). Clinically important reductions in maximum flow correlating with stress-induced ischemia on SPECT generally are associated with absolute flow reserve values below 2 (see **Chapter 16**).¹⁸ Absolute flow reserve is not only altered by factors that affect maximal coronary flow (e.g., stenosis severity, impaired microcirculatory control, arterial pressure, heart rate) but also by the corresponding resting flow value. As noted previously, resting flow can vary with hemoglobin content, baseline hemodynamics, and the resting oxygen extraction. Reductions in absolute flow reserve, therefore, can arise from inappropriate elevations in resting coronary flow as well as from reductions in maximal perfusion.

In the absence of diffuse atherosclerosis or LV hypertrophy, absolute flow reserve in conscious humans is similar to that measured in animals, with vasodilated flow reaching four to five times the value at rest. Thus fairly good reduplication of the idealized relation between stenosis severity and absolute flow reserve occurs in patients with isolated one- or two-vessel CAD (**Fig. 49-15A**) with intracoronary papaverine-induced vasodilation. By contrast, abnormalities in the coronary microcirculation as well as uncertainty in stenosis geometry or diffuse atherosclerosis leads to considerably more variability of the observed relation between stenosis severity and absolute flow reserve in patients with more extensive disease (**Fig. 49-15B**). Part of this reflects the fact that patients with risk factors for CAD such as hypercholesterolemia and no significant coronary luminal narrowing have microcirculatory impairment in flow or attenuated vasodilator responsiveness, with absolute flow reserve using PET being lower than in normal subjects. Thus a significant limitation of absolute flow reserve measurements is that the importance of an epicardial stenosis cannot be dissociated from changes due to functional abnormalities in the microcirculation that are common in patients (e.g., hypertrophy and impaired endothelium-dependent vasodilation). Likewise, recent studies have also identified abnormalities in coronary flow regulation in metabolic syndrome.²⁰

Relative Flow Reserve. Relative coronary flow reserve measurements are the cornerstone of noninvasive identification of hemodynamically important coronary stenoses using nuclear perfusion imaging (see **Chapter 16**). In this approach, relative differences in regional perfusion (per gram of tissue) are assessed during maximal pharmacologic vasodilation or exercise stress and expressed as a fraction of flow to normal regions of the heart (see **Fig. 49-14B**). This approach compares relative perfusion states under the same hemodynamic conditions and is fairly insensitive to variations in mean arterial pressure, heart rate, and preload. An alternative approach uses invasive absolute flow reserve measurements and derives relative flow reserve by dividing absolute flow reserve in a stenotic vessel by absolute flow reserve in a remote normally perfused territory.¹⁸

Although widely used to identify hemodynamically significant stenoses, significant limitations arise in using imaging to quantify relative flow reserve. First, conventional SPECT imaging requires a normal reference segment within the left ventricle for comparison. Because of this, relative flow reserve measurements cannot accurately quantify stenosis severity when diffuse abnormalities in flow reserve related to either balanced multivessel CAD or impaired microcirculatory vasodilation are present. Large differences in relative vasodilated flow are

FIGURE 49-14 Interrelation of absolute flow reserve, relative flow reserve, and FFR. **A**, Absolute flow reserve is the ratio of coronary flow during vasodilation to the resting value. It can be obtained with invasive measurements of intracoronary flow velocity or quantitative kinetic perfusion measurements with PET. **B**, Relative flow reserve compares maximal vasodilated flow in a stenotic region with an assumed normal region in the same heart and is most commonly measured with perfusion imaging during stress. **C**, FFR is conceptually similar to relative flow reserve and assesses maximal flow indirectly from coronary pressure measurements distal to a stenosis during vasodilation. Absolute flow reserve reflects the summed effects of a stenosis as well as abnormalities in the coronary microcirculation. By contrast, relative flow reserve and FFR identify the relative effects of a stenosis compared with a normal vessel. They assume maximal vasodilatory responses of coronary resistance vessels and cannot identify the potential contribution of abnormalities in microcirculatory resistance control to the development of myocardial ischemia.

FIGURE 49-15 Absolute coronary flow reserve as a function of stenosis severity in patients. **A**, Measured absolute flow reserve after intracoronary papaverine vasodilation in single-vessel disease without hypertrophy demonstrates a good correlation with values predicted theoretically. **B**, Absolute flow reserve assessed using intraoperative epicardial Doppler flow measurements after onset of reactive hyperemia to a 20-second occlusion in patients with diffuse multivessel coronary artery disease. For all vessels, there is a poor relation with stenosis severity. This reflects variability in stenosis severity with visual interpretation, as well as abnormal microcirculatory responses to ischemia and multiple risk factors for impaired endothelial function. LAD = left anterior descending artery; RCA = right coronary artery. (**A**, Modified from Wilson RF, Marcus ML, White CW: Prediction of the physiologic significance of coronary arterial lesions by quantitative lesion geometry in patients with limited coronary artery disease. *Circulation* 75:723, 1987; **B**, modified from White CW, Wright CB, Doty DB, et al: Does visual interpretation of the coronary arteriogram predict the physiologic importance of a coronary stenosis? *N Engl J Med* 310:819, 1984.)

required to detect SPECT perfusion differences because nuclear tracers become diffusion-limited and their myocardial uptake fails to increase proportionally with increases in vasodilated flow (see Chapter 16). As a result, differences in tracer deposition will variably underestimate the actual relative difference in perfusion. This problem can be overcome with use of PET tracers of perfusion and appropriate kinetic modeling to quantify flow. Finally, although prognostic data related to the perfusion deficit size are available, no imaging studies have been conducted to evaluate the quantitative severity of the stress or vasodilated flow reduction as a continuous outcome measure; conceptually, however, this should be similar to fractional flow reserve.

Fractional Flow Reserve. Considerable focus has turned toward invasive point-of-care approaches that use pressure measurements made distal to a coronary stenosis as an indirect index of stenosis severity (see Fig. 49-13).¹⁸ This technique, pioneered by Pijls and colleagues,²¹ is based on the principle that the distal coronary pressure measured during vasodilation is directly proportional to maximum vasodilated perfusion (see Fig. 49-14C). Fractional flow reserve (FFR) (see Chapters 54 and 55) is an indirect index determined by measuring the driving pressure for microcirculatory flow distal to the stenosis

FIGURE 49-16 PCI guided by assessing the physiologic significance of a coronary stenosis using FFR is associated with significant reductions in coronary events. Patients randomly assigned to an angiography-guided strategy based on stenosis severity had higher rates of the combined endpoint of death, myocardial infarction, and repeat revascularization versus patients whose management was guided by a FFR (less than 0.80). Individual secondary endpoint trends also favored management based on FFR (see Fig. e49-3). (From Tonino PA, De Bruyne B, Pijls NH, et al: Fractional flow reserve versus angiography for guiding percutaneous coronary intervention. *N Engl J Med* 360:213, 2009.)

(distal coronary pressure minus coronary venous pressure) relative to the coronary driving pressure available in the absence of a stenosis (mean aortic pressure minus coronary venous pressure). The approach assumes linearity of the vasodilated pressure-flow relation (which is known to be curvilinear at reduced coronary pressure²²) and usually assumes that coronary venous pressure is zero. This results in the simplified clinical FFR index of mean distal coronary pressure/mean aortic pressure (P_d/P_{ao}). Although derived, the measurements are conceptually similar to those of relative coronary flow reserve because they only rely on minimum mean coronary pressure measurements during intracoronary vasodilation and compare stenotic with normal regions under similar hemodynamic conditions. They are attractive for clinical use in that they can immediately assess the physiologic significance of an intermediate stenosis to help guide decisions regarding coronary intervention and are unaffected by alterations in resting flow (see Chapter 55). Similarly, because they require only vasodilated coronary pressure determinations, FFR can be used to assess the functional effects of a residual lesion after percutaneous coronary intervention (PCI).

A significant advantage of FFR is the availability of now-considerable prognostic information, including recent data from a large prospective randomized study indicating that FFR measurements greater than 0.75 are associated with excellent outcomes with deferred rather than prophylactic intervention (see Chapters 54 and 55).²³ Physiologically guided PCI using FFR versus angiographic criteria was safe and cost-effective and reduced the number of stents required to treat patients with multivessel CAD. Furthermore, the ischemia-driven strategy, based on physiologic assessment of stenoses, was accompanied by a significant reduction in major adverse cardiac events at 1 year (13.2% using FFR versus 18.3% in angiographically guided treatment) (Fig. 49-16 and Fig. e49-3). In a subsequent trial, the same investigators showed that FFR-guided coronary intervention provided additional benefit over optimal medical therapy alone.²⁴ Thus patients with a FFR below 0.80 who underwent a coronary intervention on top of optimal medical therapy displayed a reduction in the need for urgent revascularization triggered by a myocardial infarction or evidence of ischemia on an electrocardiogram (ECG), as compared with patients receiving optimal medical therapy alone. Collectively, these studies support the importance of ischemia in determining prognosis and the use of a physiologic guided approach to determining the need for percutaneous coronary intervention in stable ischemic heart disease.

Unfortunately, FFR can assess only the functional significance of epicardial artery stenoses and cannot assess limitations in myocardial perfusion that arise from abnormalities in microcirculatory flow reserve in coronary resistance vessels. While simple, FFR measurements are also critically dependent on achieving maximal

FIGURE e49-3 PCI guided by assessing the physiologic significance of a coronary stenosis is associated with significant reductions in coronary events. Patients randomly assigned to an angiography-guided strategy based on stenosis severity using FFR had higher rates of the combined endpoint of death, myocardial infarction, and repeat revascularization than did patients in whom management was guided by a FFR (see Fig. 49-16). Individual endpoint trends showed no difference in mortality (**A**) but higher rates of survival free from myocardial infarction (**B**) and survival free from repeat revascularization (**C**) in patients with the FFR-guided strategy. (From Tonino PA, De Bruyne B, Pijls NH, et al: *Fractional flow reserve versus angiography for guiding percutaneous coronary intervention*. *N Engl J Med* 360:213, 2009.)

pharmacologic vasodilation (underestimating stenosis severity if vasodilation is submaximal at the time of measurement). In addition, ignoring the back pressure to coronary flow by assuming that it is equal to zero and ignoring curvilinearity of the diastolic pressure-flow relation will cause the FFR to underestimate the physiologic significance of a stenosis.²² This is particularly problematic at low coronary pressures and in assessing the functional significance of coronary collaterals, where venous pressure needs to be accounted for. Finally, inserting the pressure wire across a stenosis can lead to artifactual overestimation of stenosis severity. This error can be caused by the reduction in effective intralumenal area in the presence of diffuse disease or a severe stenosis, as well as placement that results in partial occlusion of small branch vessels. Despite these concerns and its invasive nature, determination of FFR is currently the most direct way to assess the physiologic significance of individual coronary lesions.

Advantages and Limitations of Coronary Flow Reserve Measurements. Assessing qualitative perfusion differences with noninvasive imaging is useful because relative perfusion deficit size is an important determinant of prognosis (see Chapter 16). Although the clinical role of invasive measurements that quantify functional stenosis severity continues to evolve, measurement of FFR, available at the point of interventional care, has been demonstrated to favorably affect postprocedural outcomes at reduced cost. The need to use these measurements routinely in decision making for coronary interventions in patients with stable ischemic heart disease may change in future clinical care guidelines.^{18,19}

The major assumption common to all flow reserve measurements is that the administered pharmacologic vasodilator consistently achieves maximal vasodilation of the resistance vasculature in normal subjects as well as in patients with atherosclerotic disease and impaired endothelial function. The reductions in absolute flow reserve in humans with microvascular disease and angiographically insignificant stenoses (see Fig. 49-15B), as well as variability in quantitative perfusion measurements with normal epicardial arteries and coronary risk factors, indicate that this may not always be the case. The extent to which this variability is related to structural abnormalities in the microcirculation (e.g., caused by regional hypertrophy or vascular remodeling) versus functional abnormalities in the microcirculation (altered microcirculatory vasodilator response versus impaired endothelium-dependent vasodilation) remains unclear and is discussed in greater detail further on. A second limitation is that currently available approaches can measure only coronary flow reserve averaged across the entire wall of the heart. This is because they are based on invasive epicardial coronary measurements (see Chapter 55) or, in the case of imaging (e.g., SPECT), have insufficient spatial resolution to assess transmural variations in flow (see Chapter 16). An imaging technique that could assess the physiologic significance of a stenosis in the subendocardial layers would be a major advance, because this region is the most severely affected by an epicardial stenosis. This is now feasible with CMR (see Chapter 17).

Pathophysiologic States Affecting Microcirculatory Coronary Flow Reserve

Various pathophysiologic states can accentuate the effects of a fixed-diameter coronary stenosis and may precipitate subendocardial ischemia during stress in the presence of normal coronary arteries.²⁵ Thus it is important to consider measurements of stenosis severity in the context of coexisting abnormalities of coronary arterial resistance vessel control. In the former case, treatment will be directed at the epicardial stenosis, whereas in the latter, medical therapies designed to improve abnormalities in resistance vessel control will be required. The prognostic importance of abnormalities in coronary resistance vessel control is underscored by emerging data in women evaluated for chest pain thought to be of ischemic origin.²⁶ Abnormalities in coronary flow reserve and endothelium-dependent vasodilation are common in women with insignificant epicardial coronary disease, produce metabolic evidence of myocardial ischemia as assessed by magnetic resonance spectroscopy (see Chapter 17), and negatively affect prognosis.²⁷ Common factors affecting microcirculatory resistance control independently of coronary stenosis severity in patients are LV hypertrophy, coronary microvascular disease, and impaired NO-mediated resistance vessel vasodilation, which is the result of many of the risk factors for CAD.

Left Ventricular Hypertrophy

The effects of hypertrophy on coronary flow reserve are complex and need to be thought of in terms of the absolute flow level (e.g., measured with an intracoronary Doppler probe) as well as the flow per gram of myocardial tissue (Fig. 49-17A, B).²⁸ With acquired hypertrophy, resting flow per gram of myocardium remains constant, but the increase in LV mass necessitates an increase in the absolute level of resting flow (mL/min) through the coronary artery (Bache, 1988 [classic reading]). In terms of maximal perfusion, pathologic hypertrophy does not result in appreciable vascular proliferation (as opposed to physiologic hypertrophy produced by exercise training), and coronary resistance vessels remain essentially unchanged. Thus maximum absolute flow (mL/min) during vasodilation remains unchanged, but the increase in LV mass reduces the maximum perfusion per gram of myocardium. The net effect of LV hypertrophy is that coronary flow reserve at any given coronary arterial pressure is reduced in a manner that is inversely related to the change in LV mass. For example, in the absence of a change in mean aortic pressure, a twofold increase in LV mass, as is associated with severe LV hypertrophy, can reduce absolute coronary flow reserve in a nonstenotic artery from 4 to 2. This will increase the functional severity of any anatomic degree of coronary artery narrowing and can even precipitate subendocardial ischemia with normal coronary arteries.

Some degree of LV hypertrophy is common in patients with CAD, and it probably contributes to reductions in coronary flow reserve that are independent of stenosis severity. The actual coronary flow reserve in hypertrophy will be critically dependent on the underlying cause of hypertrophy and its effects on coronary driving pressure. A similar degree of hypertrophy caused by untreated systemic hypertension will be associated with a higher coronary flow reserve than in aortic stenosis, in which mean arterial pressure remains normal. Similarly, when hypertrophy results from systolic hypertension and increased pulse pressure is caused by reduced aortic compliance, the accompanying reduction in diastolic pressure can lower coronary reserve since myocardial perfusion occurs primarily in diastole.

Coronary Microvascular Disease and Dysfunction

The effects of primary coronary microvascular dysfunction (see Fig. 49-17C, D) on reducing coronary flow reserve are somewhat similar to those of LV hypertrophy but differ in terms of the effect on maximum coronary flow. As with hypertrophy, maximal flow per gram of myocardium will be normal at rest and reduced during pharmacologic vasodilation. In contrast to hypertrophy, absolute flow remains normal at rest in microvascular disease and the absolute vasodilated flow is reduced. Because absolute flow across the stenosis during vasodilation is the major determinant of the pressure drop and hence of distal coronary pressure, a similar stenosis will have a smaller pressure gradient and higher distal pressure in a patient with microvascular disease than in a patient with LV hypertrophy. Abnormalities in microvascular vasodilation may be functional rather than structural and, as discussed further on, can arise from cumulative coronary risk factors that lead to endothelial dysfunction.

Impaired Endothelium-Dependent Vasodilation in the Microcirculation

Measurements of coronary flow reserve in humans with risk factors for atherosclerosis (see Chapter 42) are systematically lower than in normal subjects without coronary risk factors, underscoring the importance of functional abnormalities in microvascular control in determining coronary flow reserve.^{29,30} Perturbations in microvascular control may arise from abnormal local resistance vessel control via impaired endothelium-dependent vasodilation arising from NO inactivation associated with risk factors for CAD. Kuo and colleagues have demonstrated that experimental hypercholesterolemia markedly attenuates the dilation of coronary arterioles in response to shear stress as well as pharmacologic agonists that stimulate NOS in the absence of epicardial stenoses (Fig. 49-18). This was reversed

FIGURE 49-17 Effects of hypertrophy and microvascular dysfunction on absolute flow (mL/min) and flow per gram of tissue (mL/min/g). With acquired hypertrophy, myocardial mass increases without proliferation of the microcirculatory resistance arteries. **A**, The increase in LV mass causes a proportional increase in absolute flow at rest although the maximum absolute flow per minute during vasodilation remains unchanged. **B**, When tissue perfusion is assessed using flow per gram of myocardium (as obtained using PET, for example), the maximum flow per gram of tissue falls inversely with the increase in LV mass. By contrast, the resting flow per gram of myocardium remains constant, because the increase in absolute resting flow is proportional to the increase in LV mass. Regardless of whether absolute flow or flow per gram is measured, the net effect of these opposing actions is to decrease coronary flow reserve at any coronary pressure in LV hypertrophy. As a result of the reduction in microcirculatory reserve in the absence of a coronary stenosis, the functional significance of a 50% stenosis (triangles) in the hypertrophied heart could approach a more severe stenosis (in the example, 70%, circles) in normal myocardium. This can even lead to ischemia with normal coronary arteries during stress. By contrast, in microvascular disease (C and D), resting flow and LV mass remain normal. Thus, under resting conditions, absolute flow and flow per gram of tissue are similar in patients with microvascular disease as compared with normal subjects. By contrast, maximum absolute flow (C) and flow per gram of tissue (D) both are reduced in microvascular disease, reflecting a functional or structural abnormality of coronary resistance vessels. CMVD = coronary microvascular dysfunction; LVH = left ventricular hypertrophy.

with L-arginine, suggesting that it reflects impaired NO synthesis or availability.

These in vitro abnormalities in NO-mediated vasodilation can be functionally significant and impair the ability of the heart to autoregulate coronary blood flow. Figure 49-19A shows the effects of inhibiting NO on the coronary autoregulatory relation in normal dogs. Although resting blood flow is not altered, there is a marked increase in the coronary pressure at which intrinsic autoregulatory adjustments become exhausted, with flow beginning to decrease at a distal

coronary pressure of 60 versus 45 mm Hg, approximately similar to the shift occurring in response to a twofold increase in heart rate. In vivo microcirculatory studies have demonstrated that inhibiting NO production prevents resistance arteries from dilating maximally in response to shear stress.^{3,4} This limiting effect probably reflects excess resistance in the transmural penetrating arteries, which are upstream of metabolic stimuli for vasodilation and extremely dependent on shear stress as a stimulus for local vasodilation. These functional abnormalities amplify the physiologic effects of a coronary

FIGURE 49-18 Flow-mediated vasodilation in coronary resistance arteries is abolished by dietary hypercholesterolemia in swine. **A**, In normal arterioles, increased flow (pressure gradient) elicits vasodilation that, similar to human vessels, is abolished by removing the endothelium (denuded). **B**, In animals with dietary hypercholesterolemia but no significant epicardial stenosis, flow-mediated vasodilation of arterioles is abolished. It was restored by administering L-arginine to increase NO production. Luminal diameters were normalized to the diameter at a luminal pressure of 60 cm H₂O in the presence of nitroprusside (10^{-4} M). Numbers of vessels (n) and average luminal diameter (d) with spontaneous tone in physiological salt solution-albumin at 60 cm H₂O are shown. Vertical bars denote mean +SEM. (Modified from Kuo L, Davis MJ, Cannon MS, et al: Pathophysiological consequences of atherosclerosis extend into the coronary microcirculation: Restoration of endothelium-dependent responses by L-arginine. *Circ Res* 70:465, 1992.)

stenosis, resulting in the development of subendocardial ischemia at a lower workload (Fig. 49-19B).

These observations in normal animals with impaired NO production appear to be relevant to pathophysiologic states associated with impaired endothelium-dependent vasodilation in humans. For example, coronary flow reserve is markedly reduced in the absence of a coronary stenosis in familial hypercholesterolemia, and improving endothelial function by lowering elevated LDL levels with statins produces a delayed improvement in coronary flow reserve in normal and stenotic arteries and also ameliorates clinical signs of myocardial ischemia.³¹ Impaired NO-mediated vasodilation probably affects the regulation of myocardial perfusion in other disease states in which endothelium-dependent vasodilation is impaired.

Impact of Microcirculatory Abnormalities on Physiologic Measures of Stenosis Severity

If microcirculatory dysfunction is absent, quantitative measures of stenosis severity during vasodilation that are derived using absolute flow reserve, relative flow reserve, and FFR should all be closely related. Unfortunately, this is the exception rather than the rule and microvascular dysfunction and/or variability in the microcirculatory response to pharmacologic vasodilation dissociates the idealized relations between various indices of coronary flow reserve for a given stenosis severity. Figure 49-20 summarizes the observed variability. The left-hand panel (Fig. 49-20A) shows the relation between paired invasive measurements of absolute flow reserve versus distal coronary pressure-derived FFR. These measurements demonstrate several points. As shown in Figure 49-15B, hemodynamically insignificant stenoses (i.e., FFR > 0.8) can have an absolute flow reserve that varies from 1 to over 5. Although this variability decreases when FFR is less than 0.8, it is still considerable until FFR falls below 0.5. Similarly, there is a wide variation between indices of absolute flow reserve and relative perfusion differences derived from quantitative PET perfusion measurements.

The variability in microvascular dysfunction and submaximal pharmacologic vasodilator responses can have a significant impact on assessing the physiologic significance of a coronary stenosis using FFR (or relative perfusion with imaging). This effect is schematized

in Figure 49-21. The two dashed lines show idealized relations between absolute flow reserve and FFR (or relative flow reserve from perfusion imaging). Microvascular dysfunction in the presence of normal coronary arteries (0% stenosis) attenuates coronary flow reserve. Conversely, for any given stenosis, the FFR measured in the presence of microvascular disease will be higher than when vasodilator responses are normal. Thus, when maximum vasodilation is not achieved, FFR will underestimate the physiologic severity of the stenosis. This probably contributes to at least some of the discordance between FFR and coronary flow reserve observed in clinical studies, underscoring the importance of combining both pressure- and flow-derived indices to assess vasodilator reserve of the total coronary vascular bed. Indeed, the availability of high-fidelity pressure and flow measurements on a single wire has now facilitated the development of approaches to assess the stenosis pressure-flow relation as well as abnormalities in microcirculatory reserve by determining FFR and absolute coronary flow reserve simultaneously. When assessed together, these measurements have the potential to identify circumstances in which mixed abnormalities from a stenosis and abnormal microcirculation contribute to the functional impact of a coronary stenosis.

CORONARY COLLATERAL CIRCULATION

After a total coronary occlusion, residual perfusion to the myocardium persists through native coronary collateral channels that open with development of an intercoronary pressure gradient between the source and recipient vessel. In most animal species, the native collateral flow during occlusion is less than 10% of the resting flow levels and is insufficient to maintain tissue viability for longer than 20 minutes. Tremendous individual variability in the function of coronary collaterals is recognized among patients with chronic stenoses. In humans without coronary collaterals, coronary pressure during balloon angioplasty occlusion falls to approximately 10 mm Hg. In other patients, collaterals proliferate to the point where they are sufficient not only to maintain resting perfusion normal but also to prevent stress-induced ischemia at submaximal cardiac workloads.

FIGURE 49-19 Impaired microcirculatory control with abnormal NO-mediated endothelium-dependent resistance artery dilation. **A**, Effects of blocking NOS with the L-arginine analogue LNAME in chronically instrumented dogs. There is an increase in the lower autoregulatory pressure limit, resulting in the onset of ischemia at a coronary pressure of 61 mm Hg versus 45 mm Hg under normal conditions that occurred without a change in heart rate. **B**, Transmural perfusion before and after blocking NO-mediated dilation with LNAME in exercising dogs subjected to a coronary stenosis. Although coronary pressure and hemodynamics were similar, blood flow was less in each layer of the heart after blocking NOS and not overcome by metabolic dilator mechanisms during ischemia. Collectively, these experimental data support the notion that abnormalities in endothelium-dependent microvascular vasodilation can amplify the functional effects of a proximal coronary stenosis. Endo = endocardium; Epi = epicardium; LNAME = N^G-nitro-L-arginine methyl ester; LNAME = N^G-nitro-L-arginine. (**A**, Modified from Smith TP Jr, Canty JM Jr: Modulation of coronary autoregulatory responses by nitric oxide: Evidence for flow-dependent resistance adjustments in conscious dogs. *Circ Res* 73:232, 1993; **B**, modified from Duncker DJ, Bache RJ: Inhibition of nitric oxide production aggravates myocardial hypoperfusion during exercise in the presence of a coronary artery stenosis. *Circ Res* 74:629, 1994.)

Ischemia does not develop during PCI balloon occlusion when FFR (based on coronary wedge pressure during occlusion minus venous pressure) is greater than 0.25.¹⁸ A large observational cross-sectional study has demonstrated that patients with elevated distal coronary pressure arising from recruitable collaterals during transient total balloon occlusion (FFR >0.25) have a lower cardiovascular event rate and improved survival (**Fig. e49-4**).³²

Arteriogenesis and Angiogenesis

Proliferation of coronary collaterals (see Chapter 20) occurs in response to repetitive stress-induced ischemia as well as the development of transient interarterial pressure gradients between the source

and recipient vessel through a process termed *arteriogenesis*.³³ Resting distal coronary pressure consistently falls as stenosis severity exceeds 70%, and the resultant interarterial pressure gradient increases endothelial shear stress in preexisting collaterals smaller than 200 μ m in diameter. This causes progressive enlargement of collaterals through a process dependent on physical forces and growth factors (particularly vascular endothelial growth factor, VEGF) that is mediated via NOS. Thus patients with impaired NO-mediated vasodilation due to coronary risk factors may have a limited ability to develop coronary collaterals in response to a chronic coronary stenosis.

Most functional collateral flow arises from arteriogenesis in existing epicardial anastomoses that enlarge into mature vessels, which can reach 1 to 2 mm in diameter.³³ Collateral perfusion also can originate from de novo vessel growth, or *angiogenesis*, which refers to the sprouting of smaller, capillary-like structures from preexisting blood vessels. These vessels may provide nutritive collateral flow when they develop in the border between ischemic and nonischemic regions. Capillary angiogenesis may also occur within the ischemic region and can reduce the intercapillary distance for oxygen exchange. Nevertheless, because capillary resistance is already a small component of microcirculatory resistance, increases in capillary density in the absence of changes in arteriolar resistance will not significantly increase myocardial perfusion.

Great interest is currently directed toward experimental interventions to improve collateral flow (e.g., recombinant growth factors, in vivo gene transfer, adult progenitor cells) (see Chapter 30). Although many interventions have been demonstrated to cause favorable angiogenesis of capillaries and improve myocardial function, few interventions have increased arteriogenesis in mature collaterals, and randomized human clinical trials have been disappointing.^{34,35} Part of this limitation may arise from the fact that no intervention has resulted in measurable increases in maximum vasodilated myocardial perfusion or coronary flow reserve indices, the sine qua non of functional collateral formation. Improvements in myocardial function have been used as an endpoint, but such improvement may occur independently of increased perfusion and arise from mechanisms that alter cardiac myocyte growth and repair rather than angiogenesis.³⁶

Regulation of Collateral Resistance

The control of blood flow to collateral-dependent myocardium is governed by a series resistance arising from interarterial collateral anastomoses, largely epicardial, as well as the native downstream microcirculation. Collateral resistance is therefore the major determinant of perfusion, and coronary pressure distal to a chronic occlusion is already near the lower autoregulatory pressure limit. Consequently, subendocardial perfusion is critically dependent on mean aortic pressure and LV preload, with ischemia easily provoked by systemic hypotension, increases in LV end-diastolic pressure, and tachycardia. Like the distal resistance vessels, collaterals constrict when NO synthesis is blocked, which aggravates myocardial ischemia and can be overcome by nitroglycerin.^{2,6} In contrast with the native coronary circulation, experimental studies have demonstrated that coronary collaterals are under tonic dilation from vasodilator prostaglandins, and blocking cyclooxygenase with aspirin exacerbates myocardial ischemia in dogs.⁶ The role of prostanooids in human coronary collateral resistance regulation is unknown.

The distal microcirculatory resistance vasculature in collateral-dependent myocardium appears to be regulated by mechanisms similar to those present in the normal circulation, but is characterized by impaired endothelium-dependent vasodilation as compared with normal vessels.⁶ Of interest, the remote normally perfused zone in collateralized hearts also shows alterations in coronary resistance vessel control, suggesting that abnormalities are not restricted to the collateral-dependent region. The extent to which these microcirculatory abnormalities alter the normal metabolic and coronary autoregulatory responses in collateral-dependent and remote myocardial regions is unknown.⁶

METABOLIC AND FUNCTIONAL CONSEQUENCES OF ISCHEMIA

Because oxygen delivery to the heart is closely coupled to coronary blood flow, a sudden cessation of regional perfusion after a thrombotic coronary occlusion quickly leads to the cessation of aerobic metabolism, depletion of creatine phosphate, and the onset of

FIGURE e49-4 Favorable effect of coronary collaterals on prognosis. Patients with collateral flow index (CFI) of 0.25 or less measured during total occlusion of a coronary artery had a worse prognosis as reflected by the combined endpoint of death or myocardial infarction. These data support the concept that preventing ischemia with physiologically functional collaterals protects the heart from irreversible injury and other coronary events. (From Meier P, Gloeker S, Rainer Z, et al: Beneficial effect of recruitable collaterals: A 10-year follow-up study in patients with stable coronary artery disease undergoing quantitative collateral measurements. *Circulation* 116:975, 2007.)

FIGURE 49-20 Wide variation in paired measurements of functional stenosis severity is observed with use of different indices of flow reserve in the same patient. **A**, Simultaneous intracoronary catheter–based measurements of absolute coronary flow reserve (CFR) are compared with FFR. **B**, Quantitative measurements of perfusion derived from PET at rest and during vasodilation compare absolute CFR with relative flow reserve (stress relative uptake). This variability reflects differences in the contribution of the microcirculation and stenosis in individual patients. (Modified from Johnson NP, Kirkendeel RL, Gould KL: Is discordance of coronary flow reserve and fractional flow reserve due to methodology or clinically relevant coronary pathophysiology? *J Am Coll Cardiol Img* 5:193, 2012.)

FIGURE 49-21 The effects of microvascular dysfunction on the stenosis pressure-flow relation and measurements of flow reserve. The upper green dashed line shows the idealized linear relation between absolute flow reserve and FFR when the coronary microcirculation is normal and maximally vasodilated. The lower red dashed line indicates the relation between absolute flow reserve and FFR when there is microvascular dysfunction. Individual stenoses are illustrated by the solid blue lines. The presence of microvascular dysfunction will limit vasodilation. Thus absolute flow reserve will be reduced and will overestimate stenosis severity. By contrast, because distal coronary pressure is higher with submaximal vasodilation, FFR (and relative flow reserve) will underestimate stenosis severity. It is likely that these interactions contribute to the variability demonstrated in Figure 49-20.

anaerobic glycolysis. This is followed by the accumulation of tissue lactate, a progressive reduction in tissue ATP levels, and an accumulation of catabolites, including those of the adenine nucleotide pool. As ischemia continues, tissue acidosis develops and there is an efflux of potassium into the extracellular space. Subsequently, ATP levels fall below those required to maintain critical membrane function, resulting in the onset of myocyte death.

Irreversible Injury and Myocyte Death

The temporal evolution and extent of irreversible tissue injury after coronary occlusion are variable and dependent on transmural

location, residual coronary flow, and the hemodynamic determinants of oxygen consumption. Irreversible myocardial injury begins after 20 minutes of coronary occlusion in the absence of significant collaterals.³⁷ Irreversible injury starts in the subendocardium and progresses as a wave front over time, from the subendocardial layers to the subepicardial layers (Fig. 49-22). This reflects the higher oxygen consumption in the subendocardium and the redistribution of collateral flow to the outer layers of the heart by the compressive determinants of flow at reduced coronary pressure. In experimental infarction, the entire subendocardium is irreversibly injured within 1 hour of occlusion, and the transmural progression of infarction is largely completed within 4 to 6 hours after coronary occlusion. Factors that increase myocardial oxygen consumption (e.g., tachycardia) or reduce oxygen delivery (e.g., anemia, arterial hypotension) accelerate the progression of irreversible injury. By contrast, repetitive reversible ischemia or angina occurring before an occlusion can reduce irreversible injury through preconditioning.³⁸

The magnitude of residual coronary flow through collaterals or through a subtotal coronary occlusion is the most important determinant of the actual time course of irreversible injury in patients with chronic CAD. The relation between infarct size and the area at risk of ischemia during a total occlusion is inversely related to collateral flow and likely explains the important role of collateral vessel function in determining prognosis.³² When subendocardial collateral flow is more than approximately 30% of resting flow values, it prevents infarction after periods of ischemia lasting longer than 1 hour. More moderate subendocardial ischemia from a subtotal occlusion (e.g., flow reduced by no more than 50%) can persist for at least 5 hours without producing significant irreversible injury.³⁹ This explains the fact that signs and symptoms of ischemia can be present for long periods without producing significant myocardial necrosis. It also explains the clinical observation that late coronary reperfusion with ongoing ischemia can salvage myocardium beyond the 6-hour time limit predicted from experimental models of infarction.

Cell death arises from multiple mechanisms in myocardial infarction (see Chapter 51).⁴⁰ Reperfusion immediately causes myocyte necrosis and sarcolemmal disruption, with the leakage of cell contents into the extracellular space. The injury is further amplified by the reentry of leukocytes into the area of injury. At later time points, myocytes initially salvaged can undergo programmed cell death or apoptosis, which can contribute to further delayed myocardial injury. Apoptosis is a coordinated involution of myocytes that circumvents

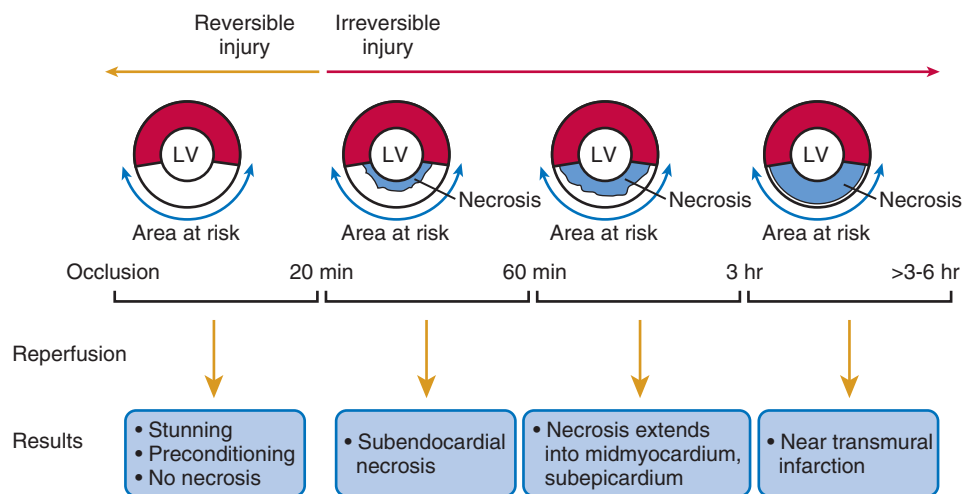

FIGURE 49-22 Wave front of necrosis in infarction. Total occlusions shorter than 20 minutes do not cause irreversible injury but can cause myocardial stunning and also precondition the heart and protect it against recurrent ischemic injury. Irreversible injury begins after 20 minutes and progresses as a wave front from endocardium to epicardium. After 60 minutes, the inner third of the left ventricular (LV) wall is irreversibly injured. After 3 hours, only a subepicardial rim of tissue remains, with the transmural extent of infarction completed between 3 and 6 hours after occlusion. The most important factor delaying the progression of irreversible injury is the magnitude of collateral flow, which is directed primarily to the outer layers of the heart. (Modified from Kloner RA, Jennings RB: *Consequences of brief ischemia: Stunning, preconditioning, and their clinical implications: Part 1. Circulation* 104:2981, 2001.)

the inflammation associated with necrotic cell death. Because apoptosis is an energy-dependent process, cells can be forced to switch to a necrotic pathway if energy levels are depleted below critical levels. In the setting of more chronic injury, autophagy can contribute to the mechanisms of myocyte death. Because of the temporal complexity of irreversible injury, the relative importance of each mechanism in myocardial infarction continues to be controversial. Nevertheless, modulating mechanisms contributing to late cell death could prevent deleterious LV remodeling.

Reversible Ischemia and Perfusion-Contraction Matching

Reversible ischemia is considerably more frequent than irreversible injury. *Supply-induced ischemia* can arise from transient coronary occlusion resulting from coronary vasospasm or transient thrombosis in a critically stenosed coronary artery, producing transmural ischemia similar to that present at the onset of infarction. *Demand-induced ischemia* arises from an inability to increase flow in response to increases in myocardial oxygen consumption in which ischemia predominantly affects the subendocardium (see Chapter 54). These have fundamentally different effects on myocardial diastolic relaxation, with supply-induced ischemia increasing LV compliance and demand-induced ischemia reducing it. There is a fairly stereotypical sequence of physiologic changes that develop during an episode of spontaneous transmural ischemia (Fig. e49-5). Coronary occlusion results in an immediate fall in coronary venous oxygen saturation, with a reduction in ATP production. This causes a decline in regional contraction within several beats reaching dyskinesia within 1 minute. As regional contraction ceases, concomitant changes include a reduction in global LV contractility (dP/dt), a progressive rise in LV end-diastolic pressure, and a fall in systolic pressure. The magnitude of the systemic hemodynamic changes varies with the severity of ischemia as well as the amount of the left ventricle subjected to ischemia. Significant electrocardiographic ST-segment changes develop within 2 minutes as efflux of potassium into the extracellular space reaches a critical level. Symptoms of chest pain are variable and usually are the last event in the evolution of ischemia. On restoring perfusion, the sequence is reversed, with resolution of chest pain occurring before hemodynamic changes resolve, but regional contraction can remain depressed, reflecting the development of stunned myocardium. A similar temporal sequence of events occurs during exercise-induced ischemia, although the time frame of evolution can be more protracted because ischemia occurs primarily in the subendocardium. Because of the temporal delay in the development of angina and other factors, many episodes of ST-segment depression are symptomatically silent. It is also likely that very brief episodes of ischemia, as reflected

by more sensitive indices, such as reduced regional contraction or elevations in end-diastolic pressure, can be electrocardiographically silent.

Acute Perfusion-Contraction Matching During Subendocardial Ischemia.

When coronary pressure distal to a stenosis falls below the lower limit of autoregulation, flow reserve is exhausted, resulting in the onset of subendocardial ischemia. In this case, reductions in subendocardial flow are closely coupled to reductions in regional contractile function of the heart as measured by sensitive approaches, such as regional wall thickening.⁴¹ An approximately linear relation has been shown between relative reductions in subendocardial blood flow and relative reductions in regional wall thickening at rest, during tachycardia, and during exercise-induced dysfunction distal to a critical stenosis⁴¹ (Fig. 49-23). This forms the basis for using regional myocardial function as an index of the severity of subendocardial ischemia during stress imaging (see Chapter 14).

Short-Term Hibernation. In steady-state ischemia, the close matching between perfusion and contraction leads to a reduced regional oxygen consumption and energy utilization, a phenomenon termed *short-term hibernation*.³⁹

This reestablishes a balance between supply and demand, as reflected by regeneration of creatine phosphate and ATP with the resolution of lactate production, despite persistent hypoperfusion. Short-term hibernation is an extremely tenuous state, and small increases in the determinants of myocardial oxygen demand precipitate further ischemia and a rapid deterioration in function and metabolism. Thus the ability of short-term hibernation to prevent necrosis is limited by the severity and duration of ischemia, with irreversible injury developing frequently after periods of more than 12 to 24 hours.³⁹

Functional Consequences of Reversible Ischemia

Various late consequences of ischemia after normal myocardial perfusion is reestablished have been documented. These reflect acute as well as delayed effects on regional function, as well as protection of the heart from subsequent ischemic episodes. In the most chronic state, they result in hibernating myocardium, characterized by chronic contractile dysfunction and regional cellular mechanisms that downregulate contractile and metabolic function of the heart so as to protect it from irreversible injury. The complex interplay among these entities is summarized in Figure 49-24. In clinical practice, it is difficult to separate all of the various mechanisms involved in contributing to ischemia-induced viable dysfunctional myocardium, because they all may coexist to some extent in the same heart. They can, however, be separated experimentally, and the important features and mechanisms from basic studies are summarized next.

Myocardial Preconditioning and Postconditioning

Brief reversible ischemia preceding a prolonged coronary occlusion reduces myocyte necrosis, a phenomenon termed *acute preconditioning*.^{38,42} Because acute infarction frequently is preceded by angina, preconditioning is an endogenous mechanism that can delay the evolution of irreversible myocardial injury. Acute preconditioning can be induced pharmacologically using adenosine A₁ receptor stimulation as well as various pharmacologic agonists that stimulate protein kinase C or open mitochondrial K_{ATP} channels. It has been demonstrated in humans during angioplasty with reduced subjective and objective ischemia during successive coronary occlusions as an endpoint. Preconditioning also develops on a chronic basis (*delayed preconditioning*) and, once induced, persists for up to 4 days.⁴³ It

FIGURE e49-5 Physiologic changes during two episodes of spontaneous asymptomatic ischemia in a patient with an acute coronary syndrome. High-speed electrocardiographic tracings depict the baseline ECG (a), pseudonormalization of T waves in early ischemia (b), and ST elevation with late ischemia (c). A primary reduction in coronary flow is depicted by the sudden fall in coronary venous oxygen saturation (CSO_2S). Shortly thereafter, left ventricular (LV) dP/dt falls, reflecting regional contractile dysfunction (solid vertical lines). Within 1 minute, LV end-diastolic pressure begins to rise (arrows) and is associated with a reduction in systolic pressure. Significant ST elevation begins after the rise in LV end-diastolic pressure (c). On spontaneous resolution of ischemia (rise in CSO_2S), the changes resolve. Each episode lasted 2 minutes and was not associated with chest pain. LVP = left ventricular pressure. (Modified from Chierchia S, Brunelli C, Simonetti I, et al: Sequence of events in angina at rest: Primary reduction in coronary flow. *Circulation* 61:759, 1980.)

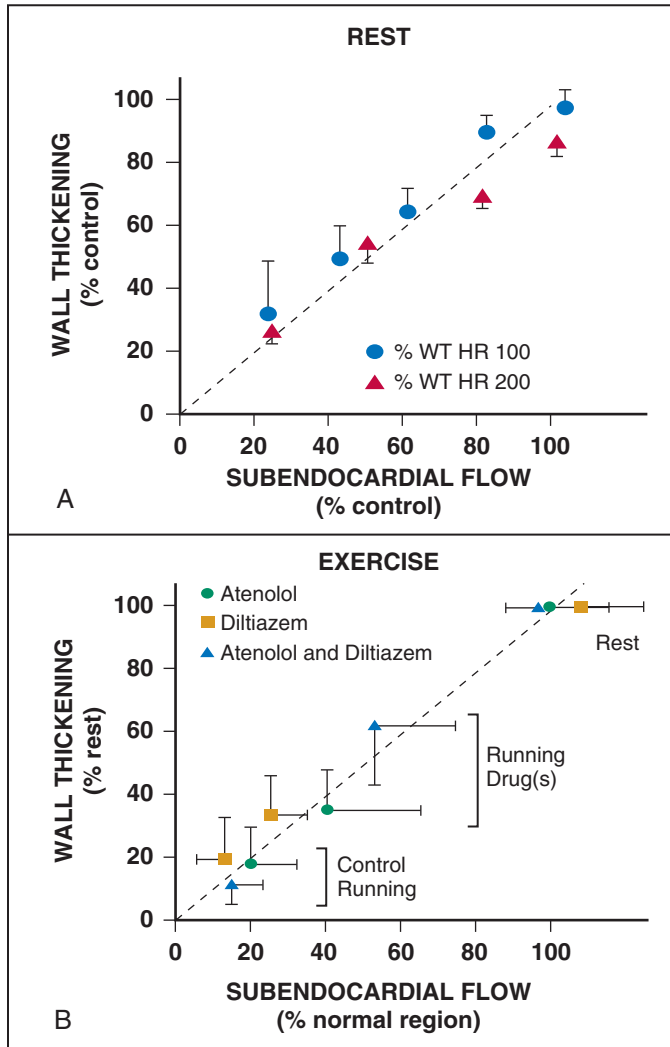

FIGURE 49-23 Perfusion-contraction matching during acute ischemia. Relative reductions in function (regional wall thickening) are proportional to the relative reduction in subendocardial flow measured with microspheres in conscious dogs. This relation is maintained over a wide range of heart rates during autoregulation (**A**) as well as during exercise with a fixed coronary stenosis (**B**). In the latter case, medical interventions that ameliorate ischemia improve both subendocardial flow and wall thickening (WT) during exercise. HR = heart rate. (**A**, Modified from Cauty JM Jr: Coronary pressure-function and steady-state pressure-flow relations during autoregulation in the unanesthetized dog. *Circ Res* 63:821, 1988; and Cauty JM Jr, Giglia J, Kandath D: Effect of tachycardia on regional function and transmural myocardial perfusion during graded coronary pressure reduction in conscious dogs. *Circulation* 82:1815, 1990; **B**, modified from Matsuzaki M, Guth B, Tajimi T, et al: Effect of the combination of diltiazem and atenolol on exercise-induced regional myocardial ischemia in conscious dogs. *Circulation* 72:233, 1985.)

reduces myocardial infarct size and protects the heart from ischemia-induced stunning. The mechanisms of chronic preconditioning involve protein synthesis, with upregulation of the inducible form of NOS (iNOS), cyclooxygenase (COX-2), and opening of the mitochondrial K_{ATP} channel. A final protective mechanism, *myocardial postconditioning*,⁴⁴ refers to the ability to cause cardiac protection by producing intermittent ischemia or administering pharmacologic agonists at the time of reperfusion. It has the great potential to affect irreversible injury because it can be induced after myocardial ischemia is established rather than requiring pretreatment³⁸ (Fig. 49-25). Protection occurs principally through activation of reperfusion injury salvage kinase pathways thereby limiting opening of the mitochondrial permeability transition pore.⁴⁵ A number of small clinical trials, using mechanical or pharmacologic postconditioning, show promise.⁴⁵ Nevertheless, large randomized controlled clinical trials

are required to prove efficacy before these novel approaches can become established adjunctive therapies in the setting of reperfusion treatment of acute myocardial infarction.⁴⁶

Stunned Myocardium

Myocardial function normalizes rapidly after single episodes of ischemia lasting less than 2 minutes. As ischemia increases in duration and/or severity, a temporal delay in the recovery of function occurs despite the fact that blood flow has been restored. Regional myocardial function remains depressed for up to 6 hours after resolution of ischemia following a 15-minute occlusion in the absence of tissue necrosis, a phenomenon called *myocardial stunning*⁴² (Fig. 49-26). A defining feature of isolated myocardial stunning is that function remains depressed while resting myocardial perfusion is normal.⁴¹ Thus there is a dissociation of the usual close relation between subendocardial flow and function. Stunned myocardium also develops after demand-induced ischemia. For example, exercise-induced ischemia can result in depressed regional function distal to a coronary stenosis for hours after perfusion is restored, and repetitive ischemia can lead to cumulative stunning. Prolonged sublethal ischemia, as seen in short-term hibernation, leads to stunning on restoration of perfusion that may take up to a week to resolve in the absence of necrosis and may be an important cause of reversibly dysfunctional myocardium in the setting of an acute reduction in flow as in an acute coronary syndrome. Stunned myocardium is also responsible for postoperative pump dysfunction after cardiopulmonary bypass. Finally, areas of stunned myocardium can coexist with irreversibly injured myocardium, contributing to time-dependent improvements in function after myocardial infarction.

Acutely stunned myocardium is clinically important to recognize, because contractile function normalizes during stimulation with various inotropic agents, including beta-adrenergic agonists. In contrast with other dysfunctional states, function will spontaneously normalize within 1 week, provided that there is no recurrent ischemia. If repetitive episodes of reversible ischemia develop before function normalizes, they can cause a state of persistent dysfunction or chronic stunning. The cellular mechanism of stunning probably involves free radical-mediated myocardial injury and reduced myofilament calcium sensitivity (Bolli and Marban, 1999 [classic reading]).

Chronic Hibernating Myocardium

Viable dysfunctional myocardium is defined as any myocardial region in which contractile function improves after coronary revascularization.^{47,48} This broad definition of reversible dyssynergy includes three distinct categories with fairly diverse pathophysiologic mechanisms that are summarized in Table 49-2. Complete normalization of function is the rule after acute ischemia but the exception in chronically dysfunctional myocardium. Brief occlusions or prolonged moderate ischemia (short-term hibernation) will result in postischemic stunning in the absence of infarction, with complete functional recovery occurring rapidly (within 1 week after reperfusion). The time course of improvement is roughly dependent on the duration and severity of the ischemic episode. Reversible dyssynergy with delayed functional improvement can also arise from structural remodeling of the heart that is independent of ischemia or a coronary stenosis (e.g., remote myocardial remodeling in heart failure or the reduced infarct volume that occurs over the initial weeks after coronary reperfusion). The latter conditions can be readily identified when the clinical setting, coronary anatomy, and assessment of myocardial perfusion are taken into account. Many clinical studies have evaluated the presence of contractile reserve during dobutamine administration as a predictor of functional recovery. Although this identifies the likelihood of functional recovery (see Chapter 14), it cannot distinguish the diverse pathophysiologic states underlying reversible dyssynergy. Understanding the cause may be important to the extent that it affects the time course and magnitude of functional recovery after revascularization in patients undergoing revascularization to treat ischemic heart failure.⁴⁸

Chronic segmental dysfunction arising from repetitive episodes of ischemia (frequently clinically silent) is common and present in at

CONSEQUENCES OF ACUTE ISCHEMIA

CONSEQUENCES OF CHRONIC REPETITIVE ISCHEMIA

B

FIGURE 49-24 Effects of ischemia on LV function and irreversible injury. The ventriculograms illustrate contractile dysfunction (dashed lines and arrows). **A**, Consequences of acute ischemia. A brief total occlusion (right) or a prolonged partial occlusion (caused by an acute high-grade stenosis, left) leads to acute contractile dysfunction proportional to the reduction in blood flow. Irreversible injury begins after 20 minutes after a total occlusion but is delayed for up to 5 hours after a partial occlusion (or with significant collaterals) caused by short-term hibernation. When reperfusion is established before the onset of irreversible injury, stunned myocardium develops, and the time required for recovery of function is proportional to the duration and severity of ischemia. With prolonged ischemia, stunning in viable myocardium coexists with subendocardial infarction and accounts for a variable amount of irreversible dysfunction. Experimental infarct size can be reduced by cardioprotective mechanisms. Intermittent occlusion at the time of reperfusion (postconditioning) can limit infarct size. Likewise, brief episodes of ischemia preceding prolonged ischemia elicit protection against infarction from prolonged ischemia (preconditioning). **B**, Effects of chronic repetitive ischemia on function distal to a stenosis. As stenosis severity increases, coronary flow reserve decreases and the frequency of reversible ischemia increases. Reversible repetitive ischemia initially leads to chronic preconditioning against infarction and stunning (not shown). Subsequently, there is a gradual progression from contractile dysfunction with normal resting flow (chronically stunned myocardium) to contractile dysfunction with depressed resting flow (hibernating myocardium). This transition is related to the physiologic significance of a coronary stenosis and can occur in a time period as short as 1 week or develop chronically in the absence of severe angina. The cellular response during the progression to chronic hibernating myocardium is variable, with some patients exhibiting successful adaptation with little cell death and fibrosis and others developing degenerative changes difficult to distinguish from subendocardial infarction. See text for further discussion.

FIGURE 49-25 The concept of lethal reperfusion injury. During ischemia, irreversible cell injury leading to cell death occurs within the ischemic risk zone in a time-dependent manner. In the absence of reperfusion, ischemic injury will progressively kill more and more cells (*dashed line*). Reperfusion stops the process of ischemic cell death but in its early stages imposes injury that results in further cell death. This is beyond the damage that would be produced by ischemia alone and is termed *lethal reperfusion injury*. The net result is that the reperfused tissue still sustains less cell death than would occur in ischemic tissue without reperfusion. Targeting cell death due to reperfusion injury has the potential to maximize cell salvage. Postconditioning applied at the onset of reperfusion limits the extent of reperfusion injury and can potentially maximize myocardial salvage. (Modified from Ovize M, Baxter GF, Di Lisa F, et al: Postconditioning and protection from reperfusion injury: Where do we stand? Position paper from the Working Group of Cellular Biology of the Heart of the European Society of Cardiology. *Cardiovasc Res* 87:406, 2010)

TABLE 49-2 Viable Dysfunctional Myocardium: Patterns of Contractile Reserve, Resting Perfusion, and Temporal Recovery of Function after Revascularization

PARAMETER	CONTRACTILE RESERVE	RESTING FLOW	EXTENT OF FUNCTIONAL RECOVERY	TIME COURSE OF RECOVERY
Transient Reversible Ischemia				
Postischemic stunning	Present	Normal	Normalizes	<24 hr
Short-term hibernation	Present	Normal	Normalizes	<7 days
Chronic Repetitive Ischemia				
Chronic stunning	Present	Normal	Improves	Days to weeks
Chronic hibernating myocardium	Variable	Reduced	Improves	Up to 12 mo
Structural Remodeling				
Subendocardial infarction	Variable	Reduced	Variable	Weeks
Remodeled, tethered myocardium	Present	Normal	Improves	Months

least one coronary distribution area in more than 60% of patients with ischemic cardiomyopathy (Fig. 49-27). When resting flow relative to a remote region is normal in dysfunctional myocardium distal to a stenosis, the region is *chronically stunned*. In contrast, when relative resting flow is reduced in the absence of symptoms or signs of ischemia, *hibernating myocardium* is present. Although previously controversy over whether flow is normal or reduced at rest has been an issue, both entities exist in patients and represent extremes in the spectrum of adaptive and maladaptive responses to chronic reversible ischemia. Viability studies are primarily required to distinguish infarction from hibernating myocardium because the myocardium is always viable when the resting flow is normal.³⁹

It was originally thought that hibernating myocardium arose from a primary reduction in flow similar to experimental models of prolonged moderate ischemia and short-term hibernation. Whereas this is a plausible mechanism for the development of hibernating myocardium in association with an acute coronary syndrome, experimental studies have subsequently demonstrated that delayed subendocardial infarction is the rule rather than the exception when moderate flow reductions are maintained for more than 24 hours.³⁹ Many

patients with hibernating myocardium present with LV dysfunction rather than symptomatic ischemia. Serial studies in animals (Fallavollita et al., 1997 [classic reading]) have now demonstrated that the reductions in relative resting flow are a consequence rather than a cause of the contractile dysfunction.⁴¹ This paradigm, relevant to chronic CAD, was proposed after experimental studies with a slowly progressive left anterior descending artery stenosis demonstrated that dysfunction with normal resting flow, consistent with chronic stunning, precedes the development of hibernating myocardium after 3 months^{41,49} (Fig. 49-28). The progression from chronically stunned myocardium (with normal resting flow) to hibernating myocardium (with reduced flow) is related to the functional significance of the chronic stenosis supplying the region and is probably a reflection of its propensity to develop repetitive supply or demand-induced ischemia. This progression can be seen in as little as 1 week after placement of a critical stenosis that exhausts coronary flow reserve.⁵⁰ As regional dysfunction progresses from chronically stunned to hibernating myocardium, the myocyte takes on regional characteristics similar to those from an explanted heart with advanced failure. Normally perfused remote zone cardiac

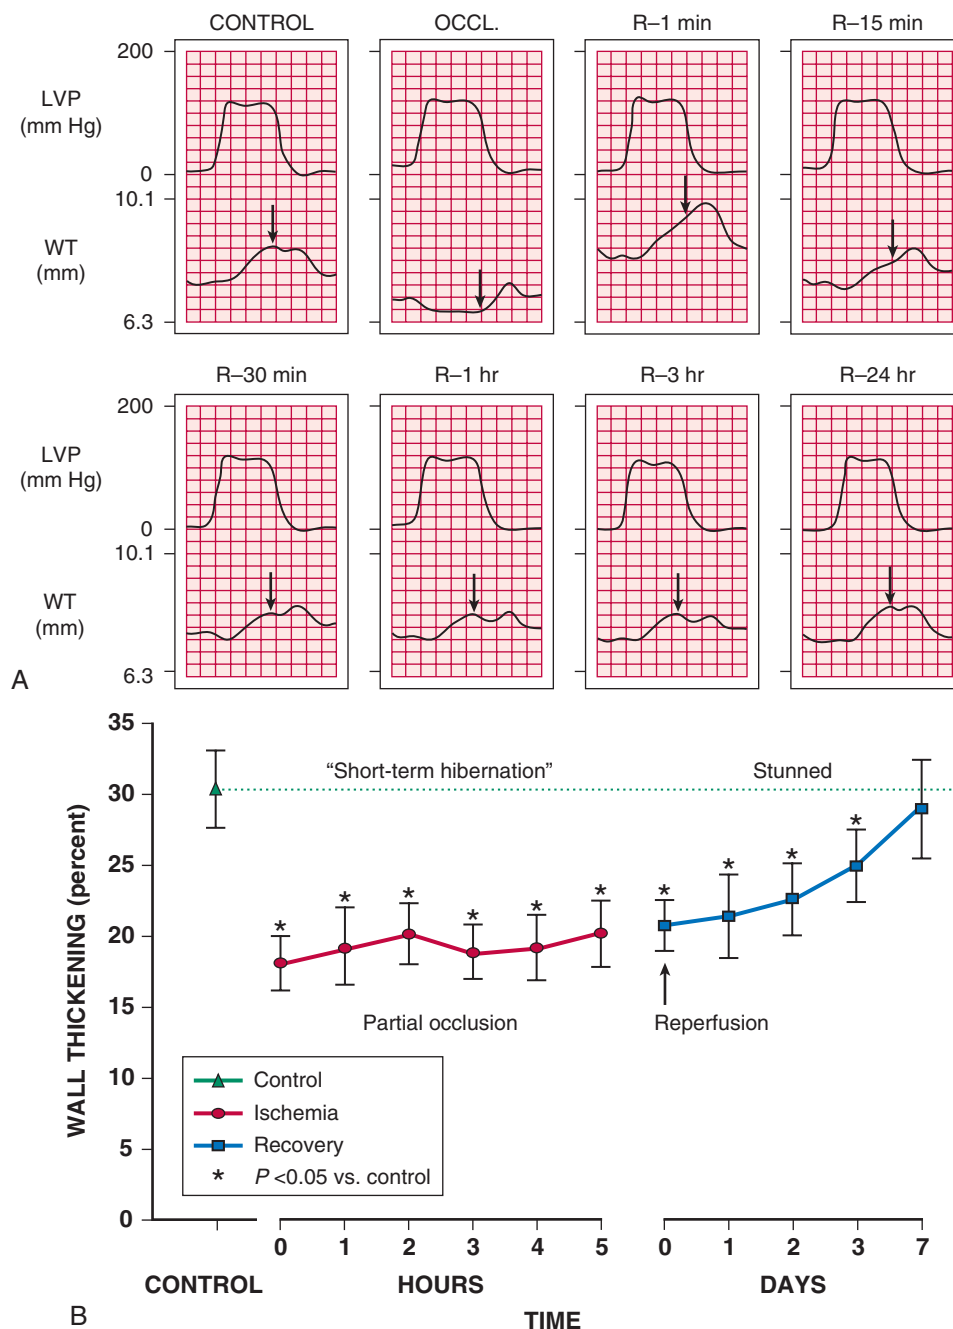

FIGURE 49-26 Stunned myocardium. **A**, Myocardial stunning after a brief total occlusion (OCCL). Wall thickening (WT) measured by ultrasonic crystals is dyskinetic, with systolic thinning during occlusion. After reperfusion (R), function is completely normal after 24 hours. **B**, Myocardial stunning after a prolonged partial occlusion. During acute ischemia (red circles), there is short-term hibernation, reflecting an acute match between reduced flow, wall thickening, and metabolism. With reperfusion (blue squares), WT remains depressed and gradually returns to normal after 1 week. LVP = left ventricular pressure. (**A**, Modified from Heyndrickx GR, Baig H, Nellens P, et al: Depression of regional blood flow and wall thickening after brief coronary occlusions. *Am J Physiol* 234:H653, 1978; **B**, modified from Matsuzaki M, Gallagher KP, Kemper WS, et al: Sustained regional dysfunction produced by prolonged coronary stenosis: Gradual recovery after reperfusion. *Circulation* 68:170, 1983.)

myocytes can be normal or take on structural alterations similar to the dysfunctional region. Some of the major cellular responses are summarized here.

Apoptosis, Myocyte Loss, and Myofibrillar Loss. The frequency of focal myocyte death from apoptosis varies during the development of viable dysfunctional myocardium and thus is probably responsible for the variability in the frequency of apoptosis when analyzing biopsies from patients.^{51,52} Experimentally, apoptosis is particularly prominent during the transition from chronically stunned to hibernating myocardium, at which time there is a loss of approximately 30% of the regional myocytes (Fig. 49-29 and Fig. e49-6). The myocyte loss

results in compensatory regional myocyte hypertrophy to maintain approximately normal wall thickness. Light microscopic and ultrastructural characteristics of hibernating myocardium from transmural biopsy samples are characterized by small increases in interstitial connective tissue, myofibrillar loss (myolysis), increased glycogen deposition, and mini-mitochondria. Experimental animal models of hibernating myocardium also develop these structural changes in as little as 2 weeks, but they also are present in remote, normally perfused regions of the heart.^{39,53} Global cellular changes also have been reported in patients in the absence of a stenosis, suggesting that the structural changes probably are the result of chronically elevated preload. Thus, although cellular dedifferentiation had been

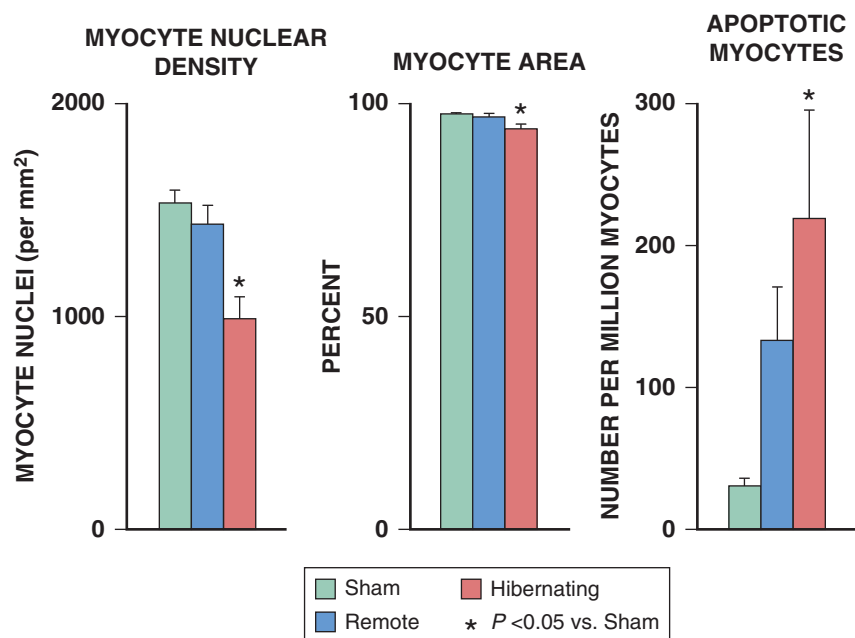

FIGURE e49-6 Progressive myocyte loss and compensatory cellular hypertrophy in hibernating myocardium. Data for hibernating LAD regions are compared with those for remote regions as well as with those for LAD regions from normal animals. The progression from chronically stunned to hibernating myocardium is accompanied by regional myocyte apoptosis. Although this occurs in only 1 in 5000 myocytes at any instant in time, it is a continuous process that over several months leads to substantial myocyte loss. The result is an approximately 30% reduction in myocyte nuclear number without significant fibrosis, because the myocyte area remains essentially normal. The latter is the result of compensatory myocyte cellular hypertrophy (see Fig. 49-29). (From Lim H, Fallavollita JA, Hard R, et al: *Profound apoptosis-mediated regional myocyte loss and compensatory hypertrophy in pigs with hibernating myocardium*. *Circulation* 100:2380, 1999.)

FIGURE 49-27 Hibernating myocardium in humans with a chronic LAD occlusion and collateral-dependent myocardium. The RAO tracing of the left ventriculogram shows anterior akinesis (*upper left*). Transaxial PET scans illustrate $^{13}\text{NH}_3$ flow measurements at rest (*lower left*) and after pharmacologic vasodilation with dipyridamole (*lower right*). Quantitative perfusion measurements showed LAD flow to be critically impaired. Viability (after an oral glucose load) is identified by increased ^{18}F -2-fluoro-2-deoxyglucose (FDG) uptake in the anterior wall (*upper right*). LAD = left anterior descending artery; RAO = right anterior oblique. (Modified from Vanoverschelde JL, Wijns W, Depre C, et al: Mechanisms of chronic regional postischemic dysfunction in humans: New insights from the study of noninfarcted collateral-dependent myocardium. *Circulation* 87:1513, 1993.)

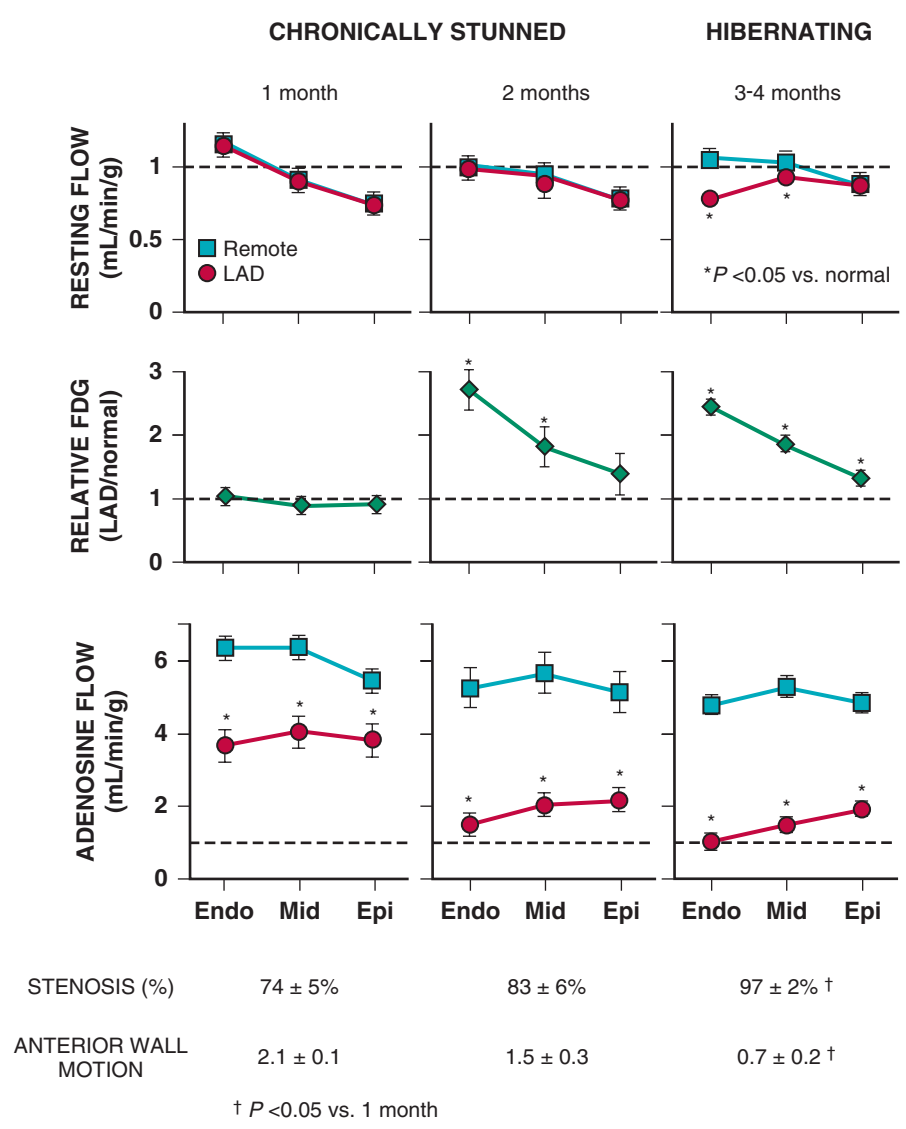

FIGURE 49-28 Progression from chronically stunned to hibernating myocardium as stenosis severity increases in swine with viable dysfunctional myocardium from a chronic LAD stenosis. Transmural flow measurements (microspheres) at rest and adenosine vasodilation are shown, along with regional FDG uptake (under fasting conditions). Shown below are the angiographic stenosis severity and anterior wall motion score—3, normal; 2, mild hypokinesis; 1, severe hypokinesis; 0, akinesis. As stenosis severity increases over time, there is a reduction in vasodilated flow (adenosine) to the LAD region. Initially, there is anterior hypokinesis, with normal resting flow consistent with chronically stunned myocardium. After 3 months, the stenosis progresses to occlusion with collateral-dependent myocardium. Subendocardial flow is critically reduced and there is a reduction in resting flow to the inner two thirds of the LAD myocardium. At this time, hibernating myocardium is present, and there is no evidence of infarction. The temporal progression of abnormalities demonstrates that chronic stunning precedes the development of hibernating myocardium. In contrast with short-term hibernation resulting from acute ischemia, the reduction in resting flow is a consequence, rather than a cause, of the contractile dysfunction. Endo = endocardium; Epi = epicardium; FDG = ^{18}F -2-fluoro-2-deoxyglucose; LAD = left anterior descending artery. (Modified from Fallavollita JA, Canty JM Jr: Differential ^{18}F -2-deoxyglucose uptake in viable dysfunctional myocardium with normal resting perfusion: Evidence for chronic stunning in pigs. *Circulation* 99:2798, 1999.)

FIGURE 49-29 Myocyte cellular changes in hibernating myocardium. The increased myocyte apoptosis (see Fig. e49-6) results in compensatory myocyte cellular hypertrophy in hibernating myocardium. Although reticular collagen is regionally increased (approximately 2%), there is no evidence of infarction. The electron microscopic characteristics of hibernating myocardium (myolysis, glycogen) demonstrate myofibrillar loss, an increased number of small mitochondria, and increased glycogen content. Although these are markedly different from normal myocardium (sham), biopsy samples from normal remote, nonischemic segments show similar electron microscopic changes, indicating that these ultrastructural abnormalities are not directly related to ischemia, nor are they the cause of regional contractile dysfunction. LAD = left anterior descending coronary artery territory. (From Canty JM, Fallavollita JA: Hibernating myocardium. *J Nucl Cardiol* 12:104, 2005.)

emphasized as a mechanism of adaptation, the global ultrastructural changes probably are not causally related to the regional responses to ischemia in hibernating myocardium.^{39,48}

Cell Survival and Antiapoptotic Program in Response to Repetitive Ischemia. Variability in the regulation of cell survival pathways in response to repetitive ischemia has been well documented. Some studies have demonstrated upregulation of cardioprotective mechanisms in response to repetitive reversible ischemia, which may be operative in minimizing myocyte cell death and fibrosis in the chronic setting.⁵⁴ An interesting mechanism potentially linking altered metabolism and protection is the regional downregulation of glycogen synthase kinase-3 β , which can ameliorate cell death and also explain the increased tissue glycogen in hibernating myocardium.⁵⁵ In experimental studies in animals without heart failure, antiapoptotic and stress proteins such as HSP-70 have been found to be upregulated,⁵⁶ whereas increased proapoptotic proteins and a profile of progressive cell death and fibrosis have been reported in human biopsies of patients with hibernating myocardium and heart failure.⁵² This variability among reported studies probably reflects the frequency and severity of ischemia, modulation by neurohormonal activation in heart failure, and the complexity of the temporal expression of adaptive and maladaptive responses in myocardium subjected to chronic repetitive ischemia. In this regard, the physiologic significance of a stenosis (i.e., coronary flow reserve) has been demonstrated to be a major determinant of the intrinsic myocardial adaptations to ischemia.⁵⁷

Metabolism and Energetics in Hibernating Myocardium. Once adapted, the metabolic and contractile response of hibernating myocardium appears to be dissociated from external determinants of workload. As a result, submaximal increases in oxygen consumption can occur without immediately leading to subendocardial ischemia.⁵⁸ Experimentally, the hibernating myocardial region appears to operate over a lower range of the normal myocardial supply-demand relation in a fashion similar to that for the nonischemic failing heart. Although

glycogen content is increased, maximum rates of glucose uptake during insulin stimulation are not altered. Recently, studies of isolated mitochondria from swine with hibernating myocardium have demonstrated alterations in mitochondrial respiration⁵⁹ with a downregulation of energy utilization and oxygen consumption.⁶⁰ This slows ATP utilization and presumably maintains cell viability during superimposed acute ischemia. Proteomic analysis has demonstrated a reduction in multiple proteins involved in oxidative metabolism and electron transport.⁵⁶

Inhomogeneity in Sympathetic Innervation, Beta-Adrenergic Responses, and Sudden Death. The contractile response of hibernating myocardium is blunted and partially related to a regional downregulation in beta-adrenergic adenylyl cyclase coupling, similar to that found globally in advanced heart failure.⁶¹ This effect may be related to local norepinephrine overflow, because the presynaptic uptake of norepinephrine is reduced when assessed using nuclear tracers such as ¹¹C-hydroxyephedrine.⁶² The resultant inhomogeneity in myocardial sympathetic nerve function may be one of the reasons responsible for the vulnerability of experimental hibernating myocardium to develop lethal ventricular arrhythmias and ventricular fibrillation.⁶³ Thus reversing electrical instability as well as improving contractile dysfunction may account for the positive impact of coronary revascularization on survival.⁴⁸ Despite this effect, the extent of viable, denervated myocardium remains a strong predictor of arrhythmic death in patients with ischemic cardiomyopathy.⁶⁴

Successful Adaptation versus Degeneration in Hibernating Myocardium. There is considerable divergence among studies regarding the pathology of reversibly dyssynergic hibernating myocardium. At one extreme, some investigators believe that it is destined to undergo irreversible myocyte death, which is supported by data showing large amounts of fibrosis (more than 30% of the tissue) and markedly abnormal high-energy phosphate metabolism and by retrospective analysis suggesting that the degree of fibrosis is related to

the duration of hibernating myocardium.⁵² At the other extreme, there are circumstances in which fibrosis is not a prominent feature with normal myocardial energetics at rest, suggesting that hibernating myocardium can be sustained for long periods without progressive degeneration.^{63,65} The factors that promote a path toward progressive degeneration versus adaptation are currently unknown but may be modulated by the superimposed neurohormonal activation and elevation in cytokine levels associated with advanced clinical heart failure as well as intermittent irreversible injury that arises from intermittent reductions in coronary flow below the threshold required to maintain myocyte viability.

FUTURE PERSPECTIVES

The major factors determining myocardial perfusion and oxygen delivery that were established more than 30 years ago have been incorporated into the current management of angina and have withstood the test of time. The basic understanding of the fluid mechanical behavior of coronary stenoses also has been translated to the cardiac catheterization laboratory, where measurements of coronary pressure distal to a stenosis and coronary flow are routinely obtained. These physiologic concepts now facilitate routine clinical decision making in a fashion that favorably affects outcomes.

Despite progress in advancing our mechanistic understanding of the coronary circulation and myocardial ischemia in health and disease, important gaps remain in our basic knowledge as well as in the translation of this knowledge to clinical care. For example, why some patients develop coronary collaterals and/or intrinsic adaptations to repetitive ischemia whereas others undergo progressive structural degeneration remains unclear. Basic research has identified the importance of physical factors such as shear stress and local coronary pressure in regulating isolated coronary resistance vessels but how these interact in a complex vascular network to bring about the phenomenon of autoregulation and metabolic coronary vasodilation remains unanswered. Finally, although abnormalities in coronary microcirculatory control may be as important as stenosis severity in determining symptoms of myocardial ischemia as well as the risk for subsequent coronary events, our understanding of the physiologic and cellular mechanisms responsible for microvascular dysfunction is limited. Continued bench-to-bedside translational investigation in these and other areas is needed to advance our fundamental knowledge of coronary circulatory control and improve the care of patients with chronic ischemic heart disease.

Acute chest pain is one of the most common reasons for seeking care in the emergency department (ED), and it accounts for approximately 8 million ED visits annually in the United States. Such pain suggests acute coronary syndrome (ACS), but after diagnostic evaluation, only 15% to 25% of patients with acute chest pain actually have ACS.^{1,2} The difficulty lies in discriminating patients with ACS or other life-threatening conditions from those with noncardiovascular, non-life-threatening chest pain. The diagnosis of ACS is missed in approximately 2% of patients, which can lead to substantial consequences—for example, the short-term mortality in patients with acute myocardial infarction (MI) who are mistakenly discharged from the ED increases twofold over that expected for patients who are admitted to the hospital. For patients with a lower risk for complications, however, these concerns must be balanced against the cost and inconvenience of admission and against the risk for complications from tests and procedures with a low probability of improving patient outcomes.

Several recent advances have enhanced the accuracy and efficiency of evaluation of patients with acute chest pain, including better blood markers for myocardial injury³; decision aids to stratify patients according to their risk for complications; early exercise testing⁴; radionuclide scanning for lower risk patient subsets⁵ ([see Chapter 16](#)); multislice computed tomography for anatomic evaluation of coronary artery disease (CAD), pulmonary embolism (PE), and aortic dissection⁶ ([see Chapter 18](#)); and the use of chest pain units⁴ and critical pathways for efficient and rapid evaluation of lower-risk patients.⁷

CAUSES OF ACUTE CHEST PAIN

In a typical population of patients undergoing evaluation for acute chest pain in EDs, about 15% to 25% have acute MI or unstable angina.² A small percentage has other life-threatening problems, such as PE or acute aortic dissection, but most leave the ED without a diagnosis or with a diagnosis of a non-cardiac-related condition. Such noncardiac conditions include musculoskeletal syndromes, disorders of the abdominal viscera (including gastroesophageal reflux disease), and psychological conditions ([Table 50-1](#)).

Myocardial Ischemia or Infarction

The most common serious cause of acute chest discomfort is myocardial ischemia or infarction ([see Chapters 52 and 53](#)), which occurs when the supply of myocardial oxygen is inadequate for the demand. Myocardial ischemia usually occurs in the setting of coronary atherosclerosis, but it may also reflect dynamic components of coronary vascular resistance. Coronary spasm can occur in normal coronary arteries or, in patients with coronary disease, near atherosclerotic plaque and in smaller coronary arteries ([see Chapter 49](#)). Other less common causes of impaired coronary blood flow include syndromes that compromise the orifices or lumina of the coronary

arteries, such as coronary arteritis, proximal aortitis, spontaneous coronary dissection, proximal aortic dissection, coronary emboli from infectious or noninfectious endocarditis or thrombus in the left atrium or left ventricle, myocardial bridge, or a congenital abnormality of the coronary arteries ([see Chapter 20](#)).

The classic manifestation of ischemia is angina, which is usually described as a heavy chest pressure or squeezing, a burning feeling, or difficulty breathing ([see Chapter 11](#)). The discomfort often radiates to the left shoulder, neck, or arm. It typically builds in intensity over a period of a few minutes. The pain may begin with exercise or psychological stress, but ACS most commonly occurs without obvious precipitating factors.

Atypical descriptions of chest pain reduce the likelihood that the symptoms represent myocardial ischemia or injury. The American College of Cardiology (ACC) and American Heart Association (AHA) guidelines list the following as pain descriptions uncharacteristic of myocardial ischemia⁷:

- Pleuritic pain (i.e., sharp or knifelike pain brought on by respiratory movements or coughing)
- Primary or sole location of the discomfort in the middle or lower abdominal region
- Pain that may be localized by the tip of one finger, particularly over the left ventricular apex
- Pain reproduced with movement or palpation of the chest wall or arms
- Constant pain that persists for many hours
- Very brief episodes of pain that last a few seconds or less
- Pain that radiates into the lower extremities

Nevertheless, data from large populations of patients with acute chest pain indicate that ACS occurs in those with atypical symptoms at sufficient frequency that no single factor suffices to exclude the diagnosis of acute ischemic heart disease. Clinicians should be mindful of “angina equivalents” such as jaw or shoulder pain in the absence of chest pain or dyspnea, nausea or vomiting, and diaphoresis. In particular, women, older persons, and individuals with diabetes may be more likely to report atypical symptoms of myocardial ischemia or infarction ([see Chapter 77](#)). Data from the National Registry of Myocardial Infarction demonstrate that among patients hospitalized with MI, women—particularly young women—are significantly less likely than men to manifest chest pain. Not surprisingly, patients without chest pain had higher in-hospital mortality.⁸

Pericardial Disease

The visceral surface of the pericardium is insensitive to pain, as is most of the parietal surface. Therefore, noninfectious causes of pericarditis (e.g., uremia; [see Chapter 71](#)) usually cause little or no pain. In contrast, infectious pericarditis almost always involves the surrounding pleura, so patients typically experience pleuritic pain with breathing, coughing, and changes in position. Swallowing may induce the pain because of the proximity of the esophagus to the

**TABLE 50-1** Common Causes of Acute Chest Pain

SYSTEM	SYNDROME	CLINICAL DESCRIPTION	KEY DISTINGUISHING FEATURES
Cardiac	Angina	Retrosternal chest pressure, burning, or heaviness; radiating occasionally to the neck, jaw, epigastrium, shoulders, left arm	Precipitated by exercise, cold weather, or emotional stress; duration of 2-10 min
	Rest or unstable angina	Same as angina, but may be more severe	Typically <20 min; lower tolerance for exertion; crescendo pattern
	Acute myocardial infarction	Same as angina, but may be more severe	Sudden onset, usually lasting ≥30 min; often associated with shortness of breath, weakness, nausea, vomiting
	Pericarditis	Sharp, pleuritic pain aggravated by changes in position; highly variable duration	Pericardial friction rub
Vascular	Aortic dissection	Excruciating, ripping pain of sudden onset in the anterior aspect of the chest, often radiating to the back	Marked severity of unrelenting pain; usually occurs in the setting of hypertension or underlying connective tissue disorder such as Marfan syndrome
	Pulmonary embolism	Sudden onset of dyspnea and pain, usually pleuritic with pulmonary infarction	Dyspnea, tachypnea, tachycardia, signs of right-sided heart failure
	Pulmonary hypertension	Substernal chest pressure, exacerbated by exertion	Pain associated with dyspnea and signs of pulmonary hypertension
Pulmonary	Pleuritis and/or pneumonia	Pleuritic pain, usually brief, over the involved area	Pain pleuritic and lateral to the midline, associated with dyspnea
	Tracheobronchitis	Burning discomfort in the midline	Midline location, associated with coughing
	Spontaneous pneumothorax	Sudden onset of unilateral pleuritic pain, with dyspnea	Abrupt onset of dyspnea and pain
Gastrointestinal	Esophageal reflux	Burning substernal and epigastric discomfort, 10-60 min in duration	Aggravated by a large meal and postprandial recumbency; relieved by antacid
	Peptic ulcer	Prolonged epigastric or substernal burning	Relieved by antacid or food
	Gallbladder disease	Prolonged epigastric or right upper quadrant pain	Unprovoked or following a meal
	Pancreatitis	Prolonged, intense epigastric and substernal pain	Risk factors, including alcohol, hypertriglyceridemia, medications
Musculoskeletal	Costochondritis	Sudden onset of intense fleeting pain	May be reproduced by pressure over the affected joint; occasionally, swelling and inflammation over the costochondral joint
	Cervical disc disease	Sudden onset of fleeting pain	May be reproduced with movement of the neck
	Trauma or strain	Constant pain	Reproduced by palpation or movement of the chest wall or arms
Infectious	Herpes zoster	Prolonged burning pain in a dermatomal distribution	Vesicular rash, dermatomal distribution
Psychological	Panic disorder	Chest tightness or aching, often accompanied by dyspnea and lasting 30 min or more, unrelated to exertion or movement	Patient may have other evidence of an emotional disorder

posterior portion of the heart. Because the central diaphragm receives its sensory supply from the phrenic nerve and the phrenic nerve arises from the third to fifth cervical segments of the spinal cord, pain from infectious pericarditis is frequently felt in the shoulders and neck. Involvement of the diaphragm more laterally can lead to symptoms in the upper part of the abdomen and back, and thus create confusion with pancreatitis or cholecystitis. Pericarditis occasionally causes a steady, crushing substernal pain resembling that of acute MI.⁹

Vascular Disease

Acute aortic dissection (see Chapter 57) usually causes a sudden onset of excruciating ripping pain, the location of which reflects the site and progression of the dissection. Ascending aortic dissection tends to be manifested as pain in the midline of the anterior aspect of the chest, and posterior descending aortic dissection tends to cause pain in the back of the chest. Aortic dissections are rare, with an estimated annual incidence of 3 per 100,000, and usually occur in the presence of risk factors, including Marfan and Ehlers-Danlos

syndromes, bicuspid aortic valve, pregnancy (for proximal dissections), and hypertension (for distal dissections).

Pulmonary emboli (see Chapter 73) often cause a sudden onset of dyspnea and pleuritic chest pain, although they may be asymptomatic. The annual incidence is approximately 1 per 1000, although this number is probably an underestimate. Massive pulmonary emboli tend to cause severe and persistent substernal pain, which is attributed to distention of the pulmonary artery. Smaller emboli that lead to pulmonary infarction can cause lateral pleuritic chest pain. Hemodynamically significant pulmonary emboli may cause hypotension, syncope, and signs of right-sided heart failure. Pulmonary hypertension (see Chapter 74) can result in chest pain similar to that of angina pectoris, presumably because of right-heart hypertrophy and ischemia.

Pulmonary Conditions

Pulmonary conditions that cause chest pain generally produce dyspnea and pleuritic symptoms, the location of which reflects the site of pulmonary disease. Tracheobronchitis tends to be associated

with a burning midline pain, whereas pneumonia can produce pain over the involved lung. The pain of pneumothorax begins suddenly and is usually associated with dyspnea. Primary pneumothorax typically occurs in tall, thin young men; secondary pneumothorax occurs in the setting of pulmonary disease such as chronic obstructive pulmonary disease, asthma, or cystic fibrosis. Asthma exacerbations can be accompanied by chest discomfort, typically characterized as tightness.

Gastrointestinal Conditions

Irritation of the esophagus by acid reflux can produce a burning discomfort that may be exacerbated by alcohol, aspirin, and some foods. Symptoms are often worsened by a recumbent position and are relieved by sitting upright and with acid-reducing therapies. Esophageal spasm can produce a squeezing chest discomfort similar to that of angina. Mallory-Weiss tears of the esophagus can occur in patients who have had prolonged vomiting episodes. Severe vomiting can also result in esophageal rupture (Boerhaave syndrome) with mediastinitis. Chest pain caused by peptic ulcer disease usually occurs 60 to 90 minutes after meals and typically responds rapidly to acid-reducing therapies. This pain is generally epigastric in location but can radiate to the chest and shoulders. Cholecystitis produces a wide range of pain syndromes and generally causes right upper quadrant abdominal pain, but chest and back pain caused by this disorder is not unusual. The pain is frequently described as being aching or colicky. Pancreatitis typically causes an intense, aching epigastric pain that may radiate to the back. Relief through acid-reducing therapies is limited.

Musculoskeletal and Other Causes

Chest pain can arise from musculoskeletal disorders involving the chest wall (such as costochondritis), by conditions affecting the nerves of the chest wall (such as cervical disc disease), by herpes zoster, or following heavy exercise. Chest pain secondary to musculoskeletal causes is often elicited by direct pressure over the affected area or by movement of the patient's neck. The pain itself can be fleeting, or it can be a dull ache that lasts for hours. Panic syndrome is a major cause of chest discomfort in ED patients. The symptoms typically include chest tightness, often accompanied by shortness of breath and a sense of anxiety, and generally last 30 minutes or longer.

DIAGNOSTIC CONSIDERATIONS

Clinical Evaluation

When evaluating patients with acute chest pain, clinicians must address a series of issues related to prognosis and immediate management.¹⁰ Even before trying to arrive at a definite diagnosis, high-priority questions include the following:

- **Clinical stability:** Does the patient need immediate treatment for actual or impending circulatory collapse or respiratory insufficiency?
- **Immediate prognosis:** If the patient is currently clinically stable, what is the risk that a life-threatening condition such as ACS, PE, or aortic dissection exists?
- **Safety of triage options:** If the risk for a life-threatening condition is low, is it safe to discharge the patient for outpatient management, or should further testing or observation to guide management be undertaken?

Initial Assessment

Evaluation of a patient with acute chest pain can begin before the physician sees the patient, and thus effectiveness may depend on the actions of the office staff and other nonphysician personnel. Guidelines from the ACC and AHA⁷ (see Chapters 52 and 53, Guidelines sections) emphasize that patients with symptoms consistent with ACS

should not be evaluated solely over the telephone but should be referred to facilities that allow evaluation by a physician and recording of a 12-lead electrocardiogram (ECG).¹¹ These guidelines also recommend strong consideration of immediate referral to an ED or a specialized chest pain unit for patients with suspected ACS who experience chest discomfort at rest for longer than 20 minutes, hemodynamic instability, or recent syncope or near-syncope. Transport as a passenger in a private vehicle is considered an acceptable alternative to an emergency vehicle only if the wait would lead to a delay longer than 20 to 30 minutes.

Guidelines¹¹ recommend that patients with the following chief complaints undergo immediate assessment by triage nurses and be referred for further evaluation:

- Chest pain, pressure, tightness, or heaviness; pain that radiates to the neck, jaw, shoulders, back, or one or both arms
- Indigestion or heartburn; nausea and/or vomiting associated with chest discomfort
- Persistent shortness of breath
- Weakness, dizziness, lightheadedness, loss of consciousness

For such patients, initial assessment involves taking a history, performing a physical examination, obtaining an ECG and chest radiograph, and measuring biomarkers of myocardial injury.

History

If the patient does not need immediate intervention because of impending or actual circulatory collapse or respiratory insufficiency, the physician's assessment should begin with a clinical history that captures the characteristics of the patient's pain, including its quality, location, and radiation; the time and tempo (abrupt or gradual) of onset; the duration of symptoms; provoking or palliating activities; and any associated symptoms, particularly those that are pulmonary or gastrointestinal. ACS is typically described as a diffuse substernal chest pressure that starts gradually, radiates to the jaw or arms, worsens with exertion, and is relieved by rest or nitroglycerin. Because angina tends to be manifested in the same way in a given patient (at least if it is due to ischemia in the same territory), it is useful to compare the current episode with any previous documented episodes of angina. Studies have suggested that response to nitroglycerin may not reliably discriminate cardiac chest pain from non-cardiac-related chest pain.¹² In contrast to the tempo of the chest pain in ACS, PE, aortic dissection, and pneumothorax are all characterized by chest pain that is sudden and severe in onset. Moreover, pain that is pleuritic or positional in nature suggests PE, pericarditis, pneumonia, or a musculoskeletal condition. A review of the literature yielded eight factors from the chest pain history with a likelihood ratio for ACS significantly greater than 1 and six factors with a likelihood ratio significantly lower than 1 (Table 50-2).¹³

In addition to the characteristics of the acute episode, the presence of risk factors for atherosclerosis (e.g., advanced age, male sex, diabetes) increases the likelihood that the chest pain is resulting from myocardial ischemia. A history of MI is associated not only with a high risk for obstructive CAD but also with an increased likelihood of multivessel disease. Younger patients have a lower risk for ACS but should be screened with greater care for a history of recent cocaine use (see Chapter 68).¹⁴

Physical Examination

The initial examination of patients with acute chest pain should endeavor to identify potential precipitating causes of myocardial ischemia (e.g., uncontrolled hypertension), important comorbid conditions (e.g., chronic obstructive pulmonary disease), and evidence of hemodynamic complications (e.g., congestive heart failure, new mitral regurgitation, hypotension).⁷ In addition to vital signs, examination of peripheral vessels should include assessment for the presence of bruits or absent pulses, which suggest extracardiac vascular disease (see Chapter 68).

For patients whose clinical findings do not suggest myocardial ischemia, the search for noncoronary causes of chest pain should focus first on potentially life-threatening issues (e.g., aortic dissection, PE) and then turn to the possibility of other cardiac diagnoses

TABLE 50-2 Value of Elements of the Chest Pain History for the Diagnosis of Acute Coronary Syndrome

PAIN DESCRIPTOR	POSITIVE LIKELIHOOD RATIO (95% CI)
Increased Likelihood of AMI	
Radiation to the right arm or shoulder	4.7 (1.9-12.0)
Radiation to both arms or shoulders	4.1 (2.5-6.5)
Associated with exertion	2.4 (1.5-3.8)
Radiation to the left arm	2.3 (1.7-3.1)
Associated with diaphoresis	2.0 (1.9-2.2)
Associated with nausea or vomiting	1.9 (1.7-2.3)
Worse than previous angina or similar to previous MI	1.8 (1.6-2.0)
Described as pressure	1.3 (1.2-1.5)
Decreased Likelihood of AMI	
Described as pleuritic	0.2 (0.1-0.3)
Described as positional	0.3 (0.2-0.5)
Described as sharp	0.3 (0.2-0.5)
Reproducible with palpation	0.3 (0.2-0.4)
Inframammary location	0.8 (0.7-0.9)
Not associated with exertion	0.8 (0.6-0.9)

AMI = acute myocardial infarction; CI = confidence interval.
 Modified from Swap CJ, Nagurney JT: Value and limitations of chest pain history in the evaluation of patients with suspected acute coronary syndromes. *JAMA* 294:2623, 2005.

(e.g., pericarditis) and noncardiac diagnoses (e.g., esophageal discomfort). Aortic dissection is suggested by blood pressure or pulse disparities or by a new murmur of aortic regurgitation accompanied by back or midline anterior chest pain. A friction rub may accompany pericarditis. Differences in breath sounds in the presence of acute dyspnea and pleuritic chest pain raise the possibility of pneumothorax. Tachycardia, tachypnea, and an accentuated pulmonic component of the second heart sound (P₂) may be the major manifestations of PE on physical examination.

Electrocardiography

An ECG, a source of decisive data, should be obtained within 10 minutes after arrival for patients with ongoing chest discomfort and as rapidly as possible for patients who have a history of chest discomfort consistent with ACS but whose discomfort has resolved by the time of evaluation so that patients who might benefit from immediate reperfusion therapy (mechanical or pharmacologic) can be identified (see Chapter 12).¹¹ To that end, obtaining a prehospital ECG decreases the door-to-diagnosis time and, for ST-segment elevation MI (STEMI), the door-to-balloon time. Importantly, these gains accrue without any prolongation of scene or transport times and, in fact, with a reduction in scene and transport times for patients identified to have STEMI.¹⁵

The ECG aids in both diagnosis and prognosis. New persistent or transient ST-segment abnormalities (≥0.05 mV) that develop during a symptomatic episode at rest and resolve when the symptoms resolve strongly suggest acute ischemia and severe coronary disease. Non-specific ST-segment and T wave abnormalities are usually defined as lesser amounts of ST-segment deviation or T wave inversion of 0.2 mV or less and are not as helpful for risk stratification. The likelihood ratios for ACS with various findings on the ECG are shown in Table 50-3.¹⁶ Completely normal findings on an ECG do not exclude the possibility of ACS; the risk for acute MI is approximately 4% in patients with a history of CAD and 2% in those with no such history.¹⁷ Patients with normal or nearly normal findings on an ECG, however, have a better prognosis than do those with clearly abnormal ECGs at initial

TABLE 50-3 Value of ECG Findings for the Diagnosis of Acute Coronary Syndrome

ECG FINDING	POSITIVE LIKELIHOOD RATIO (95% CI WHERE AVAILABLE)
New ST-segment elevation ≥1 mm	5.7-53.9
New Q wave	5.3-24.8
Any ST-segment elevation	11.2 (7.1-17.8)

evaluation. Moreover, a normal ECG has a negative predictive value of 80% to 90%, regardless of whether the patient was experiencing chest pain at the time that the ECG was obtained.¹⁸ Diffuse ST-segment elevation and PR-segment depression suggest pericarditis. Right-axis deviation, right bundle branch block, T wave inversions in leads V₁ to V₄, and an S wave in lead I and Q wave and T wave inversions in lead III suggest PE.

The availability of a previous ECG improves diagnostic accuracy and reduces the rate of admission for patients with abnormal baseline tracings. Serial electrocardiographic tracings improve the clinician's ability to diagnose acute MI, particularly if combined with serial measurement of cardiac biomarkers. Continuous electrocardiographic monitoring to detect ST-segment shifts is technically feasible but makes an uncertain contribution to patient management. Posterior leads can be useful for identifying ischemia in the territory supplied by the circumflex coronary artery, which is otherwise relatively silent on ECGs.

Chest Radiography

A chest radiograph is typically obtained for all patients with chest pain. It is usually nondiagnostic in patients with ACS but can show pulmonary edema secondary to ischemia-induced diastolic or systolic dysfunction. It is more useful for diagnosing or suggesting other disorders; for example, it may show a widened mediastinum or aortic knob in patients with aortic dissection. The chest radiograph generally has normal findings in PE but can show atelectasis, an elevated hemidiaphragm, a pleural effusion, or more rarely, a Hampton hump or Westermark sign. The chest radiograph can reveal pneumonia or pneumothorax.

Biomarkers

Patients with chest discomfort possibly consistent with ACS should undergo measurement of biomarkers of myocardial injury (see Chapters 52 and 53). The preferred biomarker is cardiac troponin (T or I; cTnT or cTnI); creatine kinase MB isoenzyme (CK-MB) is less sensitive.⁷

Diagnostic Performance

Studies of the diagnostic performance of cTnI, cTnT, and CK-MB indicate that when any of these test findings are abnormal, the patient is highly likely to have ACS. Yet it is inherently challenging to define the diagnostic performance of biomarkers for MI because part of the definition of MI includes the rise and fall of a cardiac biomarker of necrosis. Nevertheless, these assays are indispensable in the diagnosis of MI, and when the totality of clinical evidence is used as the

reference standard for diagnosis, they have excellent sensitivity and specificity.

TROPONINS. Different genes encode troponins I and T in cardiac muscle, slow skeletal muscle, and fast skeletal muscle; hence, assays for cardiac troponins are more specific than assays for CK-MB for myocardial injury, and cardiac troponin is the preferred diagnostic biomarker.¹⁹ The high specificity of cardiac troponins for myocardium makes false-positive elevations (i.e., elevated cardiac troponin in the absence of myocardial injury) exceedingly rare. Rather, elevations in the absence of other clinical data consistent with ACS usually represent true myocardial damage from causes other than atherosclerotic CAD. Such damage may occur with other forms of myocardial injury, such as in the setting of myocarditis, myocardial contusion, or cardioversion or defibrillation; left ventricular strain from congestive heart failure,²⁰ hypertensive crisis, or extreme exercise; right ventricular strain from PE²¹; or other causes of acute pulmonary hypertension. Elevated levels of cardiac troponins have been reported in patients with renal disease.²² The exact mechanism remains unclear, but in patients with a clinical history suggestive of ACS, an elevated cardiac troponin level conveys a similarly increased risk for ischemic complications in patients across a broad range of renal function.²³ Elevated cardiac troponin levels can also occur in patients with severe sepsis; again, the mechanism remains unclear.

With serial sampling for up to 12 hours after arrival at the hospital, cardiac troponins offer a sensitivity higher than 95% and a specificity of 90%. Using only a single sample at initial evaluation results in substantially worse performance, with a sensitivity of just 70% to 75%. Recently, however, more sensitive assays have become available that offer a lower limit of detection and acceptable imprecision at low levels that meet the guidelines' recommendations of having a coefficient of variation of less than 10% at the 99th percentile in a normal reference population, thereby improving the ability to detect myocardial injury. When such assays are used, the sensitivity for detecting MI with a single sample at initial evaluation is approximately 90%, the specificity is approximately 90%, and the negative predictive value is approximately 97% to 99%.^{3,24,25} Specificity may decrease when applied to patients with preexisting coronary disease, but overall performance is still superior to that of current-generation assays.²⁶ Moreover, in patients initially seen within 3 hours of the onset of chest pain, such sensitive assays have an even more striking performance—a sensitivity of 80% to 85% versus approximately 55% for older assays. The area under the receiver operator characteristic curve is as high as 0.98 when using serial samples for such assays.

Moreover, investigators have now evaluated the value of a second assessment as early as 3 hours after arrival. At initial evaluation, 71% of patients had a value below the limit of detection with a corresponding 96% negative predictive value; at 3 hours, 70% of patients had a value below the 99th percentile with a corresponding negative predictive value of greater than 99%, thus suggesting that patients without biochemical evidence of myocyte injury in blood samples obtained 3 hours into their ED stay have effectively been "ruled out" as having MI.²⁷ Serial sampling also offers the ability to examine the change in troponin concentration between the two time points, with relative and particularly absolute increases above certain thresholds offering the potential for greater specificity for MI.²⁸

High-sensitivity assays with even lower limits of detection (e.g., <0.001 ng/mL or <1 pg/mL), currently in development, allow at least 50% (some ≥95%) of healthy individuals below the 99th percentile to have a measurable level of troponin.²⁹ When such assays were performed in patients with non-ST-segment elevation MI (NSTEMI), 72% had circulating troponin levels at baseline above the 99th percentile and the other 28% had levels above the limit of detection. Moreover, in patients with unstable angina (defined as lack of elevation of the troponin level with a current-generation commercial assay), 44% had circulating troponin levels above the 99th percentile, and another 52% had levels above the limit of detection at baseline; 6 to 8 hours later, these values were 82% and 18%, respectively.³⁰ Similarly, high-sensitivity assays can detect increases in circulating troponin in proportion to the amount of ischemia experienced during exercise stress

testing.³¹ When such assays are used in patients arriving at the ED with chest pain, approximately a quarter have undetectable levels with a corresponding 100% negative predictive value.²⁷ Thus, in the future, troponin may move from a semiquantitative assay (negative in most individuals, quantified in a subset) to quantifiable in all patients. The clinical implications of very low-level values reported from high-sensitivity assays will require definition.

CREATINE KINASE MB ISOENZYME. Until the advent of cardiac troponin assays, CK-MB was the biomarker of choice for the diagnosis of MI. Its major limitation is its relative lack of specificity because it can be found in skeletal muscle, tongue, diaphragm, small intestine, uterus, and prostate. Use of the CK-MB relative index (the ratio of CK-MB to total CK) partially addresses this limitation for skeletal muscle as a source. The amount of CK-MB in skeletal muscle, however, increases in patients with conditions that cause chronic muscle destruction and regeneration, such as muscular dystrophy; in patients who participate in high-performance athletics, such as marathon running; and in patients with rhabdomyolysis.³² CK-MB elevations are particularly common in ED patients because they have higher rates of histories of alcohol abuse or trauma. One advantage of CK-MB is a shorter half-life in the circulation, which makes it useful for gauging the timing of an MI (a normal CK-MB with an elevated troponin level could represent a small MI or an MI that occurred several days ago) and for diagnosing reinfarction in a patient who has experienced an MI in the past week.

OTHER MARKERS. Serum myoglobin and heart-type fatty acid binding protein are smaller molecules that diffuse through interstitial fluids more rapidly after cell death than do the larger CK and troponin molecules; they become abnormal as early as 30 minutes after myocardial injury. Neither, however, is specific to myocardial tissue. Although some data support the usefulness of these biomarkers in patients seen early after symptom onset,³³ their value in the context of high-sensitivity troponin assays remains uncertain.

Many patients with ACS, including those without evidence of myocyte necrosis, have elevated concentrations of inflammatory biomarkers such as C-reactive protein,³⁴ serum amyloid A, myeloperoxidase,³⁵ or interleukin-6. To date, no study has identified exact decision cut points or shown an incremental benefit with an admission or treatment strategy based on these new markers, thus limiting the clinical usefulness of these observations.

The U.S. Food and Drug Administration has approved ischemia-modified albumin (IMA) for clinical use. The albumin cobalt binding test for the detection of IMA is based on the observation that the affinity of the N-terminus of human albumin for cobalt is reduced in patients with myocardial ischemia.³⁶ As with the other markers, however, the clinical specificity of IMA in the broad population of patients with chest pain and suspected ACS remains an area for further investigation.

D-dimer testing is useful for patients with chest pain to help rule out PE, because a negative enzyme-linked immunosorbent assay has a negative predictive value of greater than 99% in patients with a low clinical probability (patients with a higher clinical probability should undergo an imaging study).³⁷ Similarly, a negative D-dimer has a negative predictive value of 96% for aortic dissection.³⁸

B-type natriuretic peptides (BNP and N-terminal pro-BNP) arise in the setting of increased ventricular wall stress. Natriuretic peptides commonly aid in the diagnosis of heart failure.³⁹ BNP levels can rise in the setting of transient myocardial ischemia,⁴⁰ and the magnitude of elevation in patients with ACS correlates with prognosis.⁴¹ Although elevations are not specific for ACS, adding natriuretic peptide measurements to the diagnostic algorithm does improve discrimination and results in improved reclassification.⁴²

PROGNOSTIC IMPLICATIONS OF TEST RESULTS. Abnormal levels of CK-MB, cTnI, and cTnT predict an increased risk for complications.⁷ Even if patients do not have elevations in CK-MB, cTnI and cTnT are helpful for early risk stratification in patients with acute chest pain. The notion that a patient with a slight elevation in troponin has an "infarctlet" of questionable prognostic significance should be abandoned.⁴³ The prognostic value of cTnI seems to be comparable to that of cTnT.

TABLE 50-4 National Academy of Clinical Biochemistry Recommendations for Use of Biochemical Markers for Risk Stratification in Acute Coronary Syndrome

Class I
<ol style="list-style-type: none"> 1. Patients with suspected ACS should undergo early risk stratification based on an integrated assessment of symptoms, physical examination findings, electrocardiographic findings, and biomarkers (level of evidence: C). 2. A cardiac troponin is the preferred marker for risk stratification and, if available, should be measured in all patients with suspected ACS. In patients with a clinical syndrome consistent with ACS, a maximal (peak) concentration exceeding the 99th percentile of values for a reference control group should be considered indicative of increased risk for death and recurrent ischemic events (level of evidence: A). 3. Blood should be obtained for testing on arrival at the hospital, followed by serial sampling, with the timing of sampling based on clinical circumstances. For most patients, blood should be obtained for testing on arrival at the hospital and 6 to 9 hours later (level of evidence: B).
Class IIa
<ol style="list-style-type: none"> 4. Measurement of high-sensitivity C-reactive protein (hsCRP) may be useful, in addition to a cardiac troponin, for risk assessment in patients with a clinical syndrome consistent with ACS. The benefits of therapy based on this strategy remain uncertain (level of evidence: A). 5. Measurement of B-type natriuretic peptide (BNP) or N-terminal pro-BNP (NT-proBNP) may be useful, in addition to a cardiac troponin, for risk assessment in patients with a clinical syndrome consistent with ACS. The benefits of therapy based on this strategy remain uncertain (level of evidence: A).
Class IIb
<ol style="list-style-type: none"> 6. Measurement of markers of myocardial ischemia, in addition to cardiac troponin and an ECG, may aid in excluding ACS in patients with a low clinical probability of myocardial ischemia (level of evidence: C). 7. A multimarker strategy that includes measurement of two or more pathobiologically diverse biomarkers, in addition to a cardiac troponin, may aid in enhancing risk stratification in patients with a clinical syndrome consistent with ACS. BNP and hsCRP are the biomarkers best studied via this approach. The benefits of therapy based on this strategy remain uncertain (level of evidence: C). 8. Early repeated sampling of cardiac troponin (e.g., 2-4 hours after arrival) may be appropriate if tied to therapeutic strategies (level of evidence: C).
Class III
Biomarkers of necrosis should not be used for routine screening of patients with a low clinical probability of ACS (level of evidence: C).

From Morrow DA, Cannon CP, Jesse RL, et al: National Academy of Clinical Biochemistry Laboratory Medicine practice guidelines: Clinical characteristics and utilization of biochemical markers in acute coronary syndromes. *Circulation* 115:e356, 2007.

Testing Strategy

The 2007 National Academy of Clinical Biochemistry (NACB) practice guidelines recommend measurement of biomarkers of cardiac injury in patients with symptoms that suggest ACS (Table 50-4).⁴⁴ Furthermore, patients with a very low probability of ACS should not undergo measurement of biomarkers because false-positive results could lead to unnecessary hospitalizations, tests, procedures, and complications.

The ACC, AHA, and NACB guidelines recommend cTnI or cTnT as the preferred first-line markers, but CK-MB (by mass assay) is an acceptable alternative. The preference for cardiac troponins reflects the greater specificity of these markers than CK-MB and the prognostic value of troponin elevations in the presence of normal CK-MB levels. If the initial set of markers is negative, another sample should be drawn 3 to 6 hours later.¹⁹

Decision Aids

An algorithm for the diagnostic evaluation of chest pain is presented in Figure 50-1. The history, physical examination, ECG, and biomarkers of myocardial injury can be integrated to allow the clinician to assess the likelihood of ACS and the risk for complications (Tables 50-5 and 50-6). Furthermore, in terms of prognosis, multivariable algorithms have been developed and prospectively validated, with the goal of improving risk stratification in patients with acute chest pain. These algorithms can be used to estimate the probability of acute MI, acute ischemic heart disease, or the risk for major cardiac complications in individual patients.¹⁷ They serve mainly to identify patients who are at low risk for complications and who therefore do not require admission to the hospital or coronary care unit. Decision aids also exist for acute PE (see Chapter 73) and aortic dissection (see Chapter 57).

An accelerated diagnostic protocol using a combination of the TIMI Risk Score for unstable angina/NSTEMI, the ECG, and serial troponin measurements at initial evaluation and 2 hours later classified 20% of patients as low risk and suitable for early discharge. The rate of major adverse cardiovascular events in this low-risk group was 0.25%, which yielded a negative predictive value of 99.7%.⁴⁵

IMMEDIATE MANAGEMENT

The ACC and AHA guidelines suggest an approach to the immediate management of patients with possible ACS that integrates information from the history, physical examination, 12-lead ECG, and initial cardiac marker tests to assign patients to four categories—non-cardiac-related diagnosis, chronic stable angina, possible ACS, and definite ACS (Fig. 50-2).⁷ In this algorithm, patients with ST-segment elevations are triaged immediately for reperfusion therapy, in accordance with the ACC and AHA guidelines for acute MI. Patients with ACS who have ST wave or T wave changes, ongoing pain, positive cardiac markers, or hemodynamic abnormalities should be admitted to the hospital for the management of acute ischemia. Cost-effectiveness analyses support triage of such patients to the coronary care unit for their initial care. For patients with possible or definite ACS who do not have diagnostic ECGs and whose initial serum cardiac markers are within normal limits, observation in a chest pain unit or other non-intensive care facility is appropriate, with subsequent additional testing (see later).

Chest Pain Protocols and Units

The main elements of a typical chest pain critical pathway are included in Figure 50-2 (lower section). According to the ACC and AHA recommendations,⁷ patients with a low risk for ACS or associated complications can be observed for 6 to 12 hours while undergoing electrocardiographic monitoring and serial measurement of cardiac markers. Patients in whom evidence of ischemia or other indicators of increased risk develop should be admitted to the coronary care unit for further management. Patients in whom recurrent pain or other predictors of increased risk do not develop can be triaged for early noninvasive testing (see later) before or after discharge. Outpatient stress testing is a reasonable option if the patient is at low risk for ACS and if the testing can be accomplished within 72 hours; such a strategy has been shown to be safe. In such patients it is prudent to prescribe aspirin and possibly beta-adrenergic blocking agents (beta blockers) and to provide them with sublingual nitroglycerin.

AoD = aortic dissection; c/w = consistent with; CXR = chest x-ray; hx = history; STE = ST elevation; TEE = transesophageal echocardiography; UA = unstable angina; TWI = T wave inversion; V/Q = ventilation-perfusion scan.

To enhance the efficiency and reliability of implementation of such chest pain protocols, many hospitals triage low-risk patients with chest pain to special chest pain units.⁴ These units are often located adjacent to or within EDs. The rate of MI has been found to be approximately 1% to 2% in most such units, and they have proved to be safe and cost-saving sites of care for low-risk patients. Chest pain

units are also sometimes used for intermediate-risk patients, such as those with a previous history of coronary disease but no other high-risk predictors. In one community-based randomized trial, patients with unstable angina and an overall intermediate risk for complications had similar outcomes and lower cost if they were triaged to a chest pain unit versus conventional hospital management.

Early Noninvasive Testing Treadmill Electrocardiography

A major goal of the initial short period of observation of low-risk patients in chest pain units is to determine whether performance of exercise testing or other noninvasive tests is safe. Treadmill exercise electrocardiography is inexpensive and available at many hospitals every day, beyond traditional laboratory hours, and prospective data indicate that early exercise test results provide reliable prognostic information for low-risk patient populations. Most studies have used the Bruce or modified Bruce treadmill protocol. Multiple studies have demonstrated that in low-risk patients, exercise testing is safe and has a negative predictive value of typically greater than 99%, although the positive predictive value is frequently less than 50% (depending on the prevalence of ACS in the tested population).⁴

Patients with low clinical risk for complications can safely undergo exercise testing after 6 to 8 hours of an evaluation that reveals no evidence of myocardial ischemia.⁴ In general, protocols for early or immediate exercise testing exclude patients with electrocardiographic findings consistent with ischemia not recorded on previous tracings, ongoing chest pain, or evidence of congestive heart failure. Analyses of pooled data have suggested that the prevalence of coronary disease in populations undergoing early exercise testing averages approximately 5%, and that the rate of adverse events is negligible. The AHA has issued a scientific statement regarding the indications for and contraindications to exercise on electrocardiographic stress testing in the ED (Table 50-7).^{4,6} For low-risk patients (see Table 50-6) with no evidence of myocardial ischemia after serial

TABLE 50-7 Indications and Contraindications for Exercise Electrocardiographic Testing in the Emergency Department

Requirements before exercise electrocardiographic testing that should be considered in the ED setting:

- Two sets of cardiac enzymes at 4-hr intervals should be normal
- ECG at the time of arrival and preexercise 12-lead ECG show no significant abnormality
- Absence of rest electrocardiographic abnormalities that would preclude accurate assessment of the exercise ECG
- From admission to the time that results are available from the second set of cardiac enzymes: patient asymptomatic, lessening chest pain symptoms, or persistent atypical symptoms
- Absence of ischemic chest pain at the time of exercise testing

Contraindications to exercise electrocardiographic testing in the ED setting:

- New or evolving electrocardiographic abnormalities on the rest tracing
- Abnormal cardiac enzyme levels
- Inability to perform exercise
- Worsening or persistent ischemic chest pain symptoms from admission to the time of exercise testing
- Clinical risk profiling indicating that imminent coronary angiography is likely

ECGs and biomarkers, outpatient stress testing ideally within 24 hours, and no later than 72 hours, has proved safe.⁴

Imaging Tests

Stress echocardiography and radionuclide scans are the preferred noninvasive testing modalities for patients who cannot undergo

treadmill electrocardiographic testing because of physical disability or who have resting ECGs that confound interpretation. Imaging studies are less readily available and more expensive than exercise electrocardiography but have increased sensitivity for the detection of coronary disease and the ability to quantify the extent of and localize jeopardized myocardium. High-risk rest perfusion scans are associated with an increased risk for major cardiac complications, whereas patients with low-risk scans have low 30-day cardiac event rates (<2%).⁴⁷⁻⁴⁹

In addition to stress imaging studies to detect provokable ischemia, rest radionuclide scans can also help determine whether a patient's symptoms represent myocardial ischemia.⁵⁰ In a multicenter prospective randomized trial of 2475 adult ED patients with ongoing or recently resolved (<3 hours) chest pain or other symptoms suggestive of acute cardiac ischemia and with normal or nondiagnostic initial electrocardiographic results, patients were randomly assigned to receive the usual evaluation strategy or the usual strategy supplemented with results from acute resting myocardial perfusion imaging. The availability of scan results did not influence the management of patients with acute MI or unstable angina, but it reduced rates of hospitalization for patients without acute cardiac ischemia from 52% to 42%. Rest myocardial perfusion imaging is most sensitive if performed when a patient is experiencing ischemic symptoms, with its sensitivity progressively diminishing thereafter. Imaging should be performed within 2 hours of the resolution of symptoms, although data support its use for up to 4 hours.⁵¹ It should be noted that perfusion defects seen at rest could represent either acute ischemia or previous infarction, which can be differentiated on subsequent pain-free rest imaging.

Echocardiography can also be used, with and without stress, to detect wall motion abnormalities consistent with myocardial ischemia. The presence of induced or baseline regional wall motion abnormalities correlates with a worse prognosis. The sensitivity of stress echocardiography appears to be comparable to that of myocardial perfusion imaging (85% to 90%), and its specificity is somewhat better (80% to 95% versus 75% to 90%).⁵² As is the case for myocardial perfusion imaging, the results are less interpretable in patients with previous MI, in whom it is difficult to exclude whether the abnormalities are preexisting unless a prior study is available. Myocardial contrast-enhanced echocardiography using microbubble imaging agents offers reasonable (77%) concordance with radionuclide scanning, and the combination of regional wall motion abnormalities and reduced myocardial perfusion has a sensitivity of 80% to 90% and a specificity of 60% to 90% for ACS.⁵³

Cardiac magnetic resonance imaging (MRI) is also being explored for the assessment of patients with suspected ACS.⁵⁴ In a study that used cardiac MRI to quantify myocardial perfusion, ventricular function, and hyperenhancement in patients with chest pain, the sensitivity for ACS was 84% and the specificity was 85%. The addition of T2-weighted imaging, which can detect myocardial edema and thus help differentiate acute from chronic perfusion defects, improves the specificity to 96% without sacrificing sensitivity.⁵⁵ Integration of coronary magnetic resonance angiography is being studied.⁵⁶ Stress MRI using adenosine, although more labor-intensive, also shows excellent sensitivity and specificity.⁵⁷

In contrast to the functional imaging data from stress testing, coronary computed tomographic angiography (CTA) offers noninvasive anatomic data. Using multidetector computed tomography, coronary CTA has a sensitivity of approximately 90% and a specificity of 65% to 90% for coronary stenosis greater than 50%. Coronary CTA has been evaluated in a single-center study of patients with chest pain seen in the ED.⁵⁸ Of 368 patients with a nondiagnostic ECG and negative initial biomarker of necrosis, ACS was ultimately diagnosed in 31. Approximately half the patients were free of CAD on coronary CTA and 0% had ACS, for a negative predictive value of 100%. The remaining 50% had evidence of atherosclerosis, with 32% having minor plaque and 18% having a stenosis greater than 50%. A final diagnosis of ACS was made in 6% of those with only minor plaque and in 35% of those with a significant stenosis. The negative predictive value of coronary stenosis by coronary CTA for ACS was 98%. Thus, given the

anatomic data rather than the functional data provided, coronary CTA may best be suited to rule out rather than rule in ACS. In a multicenter trial, 1000 patients with chest pain suggestive of ACS but without clear electrocardiographic or biomarker evidence of ACS were randomized to coronary CTA versus standard of care, which included a noninvasive functional test for ischemia (exercise electrocardiography, nuclear imaging, or stress echocardiography) in three quarters of the patients. Approximately one in six patients in the coronary CTA arm also underwent a noninvasive functional study for ischemia. Coronary CTA resulted in a shorter time to diagnosis (median, 5.8 versus 21 hours), a shorter length of stay (8.6 versus 26.7 hours), and a higher proportion of patients being able to be discharged from the ED (47% versus 12%). Patients in the coronary CTA arm had higher radiation exposure (13.9 versus 4.7 mSv) and more downstream testing, with a trend toward more coronary angiography (6% versus 4%). Hospital costs were similar.⁶ The most recent ACC and AHA guidelines acknowledge coronary CTA as a reasonable alternative to stress testing in patients with low to intermediate probability of CAD.⁷

Another advantage of CTA is that it is often the test of choice for PE and for aortic dissection (see Chapters 57 and 73), and thus so-called triple-rule-out CTA can be performed to evaluate for coronary disease, PE, and aortic dissection.⁵⁹ A triple-rule-out scan requires considerably larger doses of radiation than standard coronary CTA does. Thus, it would be reasonable to restrict triple-rule-out scans to patients with a reasonable suspicion for PE or aortic dissection.

Pathologic diagnosis of myocardial infarction (MI) requires evidence of myocardial cell death caused by ischemia. Characteristic findings include coagulation necrosis and contraction band necrosis, often with patchy areas of myocytolysis at the periphery of the infarct. During the acute phase of MI, myocytes die in the infarct zone, with subsequent inflammation, clearance of necrotic debris, and repair eventuating in scar formation.

Clinical diagnosis of MI requires a clinical syndrome indicative of myocardial ischemia with some combination of evidence of myocardial necrosis on biochemical, electrocardiographic, or imaging modalities. The sensitivity and specificity of the clinical tools for diagnosing MI vary considerably depending on the timing of evaluation after the onset of infarction. Cardiac professional societies have jointly established updated criteria for the diagnosis of MI (**Table 51-1**).¹ The revised universal definition of myocardial infarction classifies MI into five types, depending on the circumstances in which the MI occurs (**Table 51-2**).¹ These revisions to the definition of MI and a shift to more sensitive biomarkers of myocardial injury have important implications not only for the clinical care of patients but also for epidemiologic study, public policy, and clinical trials.^{2,3}

The contemporary approach to patients with ischemic discomfort is to consider them to be experiencing an acute coronary syndrome (ACS), which encompasses the diagnoses of unstable angina, non-ST-segment elevation MI (NSTEMI), and ST-segment elevation MI (STEMI) (**Fig. 51-1**). The principal diagnostic tool for patients with suspected ACS is the 12-lead electrocardiogram (ECG), which discriminates those with ST-segment elevation, the subject of **Chapters 51 and 52**, and those without ST-segment elevation, the subject of **Chapter 53**.

CHANGING PATTERNS IN INCIDENCE AND CARE

Despite advances in diagnosis and management, STEMI remains a major public health problem in the industrialized world and is on the rise in developing countries (**see Chapter 1**).⁴ In the United States, almost 600,000 patients are admitted to the hospital each year with a primary diagnosis of ACS. The number exceeds 1 million with the inclusion of ACS as a secondary diagnosis.⁵ The rate of MI rises sharply in both men and women with increasing age, and racial differences exist, with MI occurring more frequently in black men and women regardless of age. The proportion of patients with ACS events who have STEMI varies across observational studies—from 29% to 47% of patients admitted with ACS. This estimate does not include “silent” MI, which may not prompt hospitalization. Between 1999 and

2008, the proportion of patients with an ACS and STEMI declined by almost 50% (**Fig. 51-2A**; **see also Fig. 53-2**).⁶

Of particular concern from a global perspective, the burden of MI in developing countries may be approaching that now afflicting developed countries.⁴ The limited resources available to treat STEMI in developing countries mandate major international efforts to strengthen primary prevention programs (**see also Chapter 1**).

IMPROVEMENTS IN OUTCOME

The overall number of deaths from STEMI has declined steadily over the past 30 years, but it has stabilized over the past decade (**Fig. 51-2B**).⁶⁻⁹ Both a decreased incidence of STEMI and a decline in the case fatality rate after STEMI have contributed to this trend.⁵ According to estimates from the American Heart Association, the short-term mortality rate of patients with STEMI ranges from 5% to 6% during the initial hospitalization and from 7% to 18% at 1 year.¹⁰ Mortality rates in clinical trial populations tend to be approximately half of those observed in registries of consecutive patients, most likely because of the exclusion of patients with more extensive comorbid medical conditions.

Improvements in the management of patients with STEMI have occurred in several phases.¹¹ The “clinical observation phase” of coronary care consumed the first half of the 20th century and focused on detailed recording of physical and laboratory findings, with little active treatment of the infarction. The “coronary care unit phase” began in the mid-1960s and emphasized early detection and management of cardiac arrhythmias based on the development of monitoring and cardioversion/defibrillation capabilities. The “high-technology phase,” heralded by the introduction of the pulmonary artery balloon flotation catheter, set the stage for bedside hemodynamic monitoring and directed hemodynamic management. The modern “reperfusion era” of STEMI care began with intracoronary and then intravenous fibrinolysis, increased use of aspirin (**see Chapter 52**), and subsequently the development of primary percutaneous coronary intervention (PCI) (**see Chapter 55**).

Contemporary care of patients with STEMI has entered an “evidence-based coronary care phase,” which is increasingly being influenced by guidelines and performance measures for clinical practice.^{10,12,13} Implementation of guideline-directed medical treatment (GDMT) and regional quality initiatives has significantly decreased heterogeneity in care, increased compliance with evidence-based therapies, and improved outcomes.^{14,15} Mandatory outcome and procedural reporting has resulted in the establishment of benchmarks for procedural success and mortality rates in patients with MI cared for at various hospitals (www.hospitalcompare.hhs.gov).

TABLE 51-1 Universal Definition of Myocardial Infarction

Criteria for Acute Myocardial Infarction
<p>The term <i>acute MI</i> should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischemia. Under these conditions any of the following criteria meet the diagnosis for MI:</p> <ul style="list-style-type: none"> • Detection of a rise and/or fall in cardiac biomarker values (preferably cTn), with at least one value above the 99th percentile of the URL and with at least one of the following: <ul style="list-style-type: none"> • Symptoms of ischemia • New or presumed new significant ST-segment T wave (ST-T) changes or new LBBB • Development of pathologic Q waves on the ECG • Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality • Identification of an intracoronary thrombus by angiography or autopsy • Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic changes on the ECG or new LBBB but death occurred before cardiac biomarkers were determined or before cardiac biomarker values would be increased. • PCI-related MI is arbitrarily defined by elevation of cTn values (to $>5 \times$ the 99th percentile of the URL) in patients with normal baseline values (≤ 99th percentile of the URL) or a rise in cTn values $>20\%$ if the baseline values are elevated and are stable or falling. In addition, either (1) symptoms suggestive of myocardial ischemia, (2) new ischemic changes on the ECG, (3) angiographic findings consistent with a procedural complication, or (4) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality is required. • Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall in cardiac biomarker values and at least one value higher than the 99th percentile of the URL. • CABG-related MI is arbitrarily defined by elevation of cardiac biomarker values (to $>10 \times$ the 99th percentile of the URL) in patients with normal baseline cTn values (≤ 99th percentile of the URL). In addition, either (1) new pathologic Q waves or new LBBB, (2) angiographically documented new graft or new native coronary artery occlusion, or (3) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality is required.
Criteria for Previous Myocardial Infarction
<p>Any one of the following criteria meets the diagnosis for prior MI:</p> <ul style="list-style-type: none"> • Pathologic Q waves with or without symptoms in the absence of nonischemic causes • Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract in the absence of a nonischemic cause • Pathologic findings of previous MI

CABG = coronary artery bypass grafting; cTn = cardiac troponin; LBBB = left bundle branch block; URL = upper reference limit.
 From Thygesen K, Alpert JS, White HD, et al: Universal definition of myocardial infarction. *J Am Coll Cardiol* 60:1581, 2012.

TABLE 51-2 Universal Myocardial Infarction Classification of Type

Type 1: Spontaneous Myocardial Infarction
Spontaneous MI related to atherosclerotic plaque rupture, ulceration, fissuring, erosion, or dissection with resulting intraluminal thrombus in one or more of the coronary arteries that leads to decreased myocardial blood flow or distal platelet emboli with ensuing myocyte necrosis. The patient may have underlying severe CAD but on occasion nonobstructive or no CAD.
Type 2: Myocardial Infarction Secondary to Ischemic Imbalance
In instances of myocardial injury with necrosis in which a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand, e.g., coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachyarrhythmias/bradyarrhythmias, anemia, respiratory failure, hypotension, and hypertension with or without LV hypertrophy.
Type 3: Myocardial Infarction Resulting in Death When Biomarker Values Are Unavailable
Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic changes on the ECG or new LBBB but death occurring before blood samples could be obtained, before cardiac biomarkers could rise, or in rare cases, when cardiac biomarkers were not collected.
Type 4a: Myocardial Infarction Related to Percutaneous Coronary Intervention
MI associated with PCI is arbitrarily defined by elevation of cTn values to $>5 \times$ the 99th percentile of the URL in patients with normal baseline values (≤ 99 th percentile of the URL) or a rise in cTn values $>20\%$ if the baseline values are elevated and are stable or falling. In addition, either (1) symptoms suggestive of myocardial ischemia, (2) new ischemic changes on the ECG or new LBBB, (3) angiographic loss of patency of a major coronary artery or a side branch or persistent slow flow or no flow or embolization, or (4) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality is required.
Type 4b: Myocardial Infarction Related to Stent Thrombosis
MI associated with stent thrombosis is detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall in cardiac biomarkers values with at least one value above the 99th percentile of the URL.
Type 5: Myocardial Infarction Related to Coronary Artery Bypass Grafting
MI associated with CABG is arbitrarily defined by elevation of cardiac biomarker values to $>10 \times$ the 99th percentile of the URL in patients with normal baseline cTn values (<99 th percentile of the URL). In addition, either (1) new pathologic Q waves or new LBBB, (2) angiographically documented new graft or new native coronary artery occlusion, or (3) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality is required.

CABG = coronary artery bypass grafting; CAD = coronary artery disease; cTn = cardiac troponin; LBBB = left bundle branch block; URL = upper reference limit.
 From Thygesen K, Alpert JS, White HD, et al: Universal definition of myocardial infarction. *J Am Coll Cardiol* 60:1581, 2012.

Limitations of Current Therapy

Rates of appropriate initiation of reperfusion therapy vary widely, with up to 30% of patients with STEMI who are eligible to receive reperfusion therapy not receiving this lifesaving treatment in some registries.¹⁶ Therefore initiatives to increase timely administration of guideline-directed reperfusion therapy are important to achieve improvements in care (see Chapter 52).

Advanced age is a principal determinant of mortality in patients with STEMI.^{17,18} Cardiac catheterization and other invasive procedures are being performed more commonly during hospitalization in elderly patients with STEMI. Nevertheless, evidence suggests that the greatest reductions in mortality in elderly patients are gained by strategies used during the first 24 hours, a time frame in which prompt and appropriate use of lifesaving reperfusion therapy is

FIGURE 51-1 Myocardial ischemia and infarction. Myocardial ischemia and infarction can result from various coronary disease processes, including vasospasm, increased myocardial demand in the setting of a fixed coronary lesion, and erosion or rupture of vulnerable atherosclerotic plaque leading to acute thrombus formation and subsequent ischemia. All result in myocardial oxygen supply-demand mismatch and can precipitate ischemic symptoms, and all processes, when severe or prolonged, will lead to myocardial necrosis or infarction. Nonthrombotically mediated events (*bottom half, left side*) typically occur without ST-segment elevations on the ECG but can have elevated levels of cardiac biomarkers if the ischemia is severe and long enough, in which case they are classified as having type II MI. The atherothrombotic lesion is the hallmark pathobiologic event of an ACS. The reduction in flow may be caused by a completely occlusive thrombus (*bottom half, right side*) or by a subtotally occlusive thrombus (*bottom half, middle*). Ischemic discomfort may occur with or without ST-segment elevation on the ECG. Of patients with ST-segment elevation, Q-wave MI ultimately develop in most, whereas non-Q-wave MI develops in a few. Patients without ST-segment elevation are suffering from either unstable angina or NSTEMI, a distinction that is ultimately made by the presence or absence of a serum cardiac marker such as CK-MB or cardiac troponin detected in blood. Non-Q-wave MI ultimately develops in most patients with NSTEMI on the ECG; Q-wave MI may develop in a few. MI that develops as the result of the atherothrombotic lesion of an ACS is classified as type I MI. (Modified from Thygesen K, Alpert JS, Jaffe AS, et al: Third universal definition of myocardial infarction. *J Am Coll Cardiol* 60:1581, 2012.)

paramount—thus emphasizing the need to extend advances in GDMT for STEMI to older adults.¹⁹

Management and outcomes of patients with STEMI appear to vary substantially depending on the volume of such patients cared for within a hospital system.^{20,21} Mortality rates in patients with STEMI are lower in hospitals with a high clinical volume, a high rate of invasive procedures, and a top ranking in quality reports. Conversely, patients with STEMI not cared for by a cardiovascular specialist have higher mortality rates. Variation also occurs in the treatment patterns of certain population subgroups with STEMI, notably women and blacks, although after adjusting for comorbid

conditions and the degree of atherosclerosis, outcomes appear to be similar.²²

PATHOLOGIC FINDINGS

Based on research beginning in the 1970s, we now recognize that almost all ACS events result from coronary atherosclerosis, generally with superimposed coronary thrombosis caused by rupture or erosion of an atherosclerotic lesion.^{23,24} Nonatherogenic forms of coronary artery disease are discussed later in this chapter, and causes of MI without coronary atherosclerosis are presented in **Table 51-3**.

TABLE 51-3 Causes of Myocardial Infarction Without Coronary Atherosclerosis

Coronary Artery Disease Other than Atherosclerosis
Arteritis Luetic Granulomatous (Takayasu disease) Polyarteritis nodosa Mucocutaneous lymph node (Kawasaki) syndrome Disseminated lupus erythematosus Rheumatoid spondylitis Ankylosing spondylitis Trauma to coronary arteries Laceration Thrombosis Iatrogenic Radiation (radiation therapy for neoplasia) Coronary mural thickening with metabolic disease or intimal proliferative disease Mucopolysaccharidoses (Hurler disease) Homocystinuria Fabry disease Amyloidosis Juvenile intimal sclerosis (idiopathic arterial calcification of infancy) Intimal hyperplasia associated with contraceptive steroids or with the postpartum period Pseudoxanthoma elasticum Coronary fibrosis caused by radiation therapy Luminal narrowing by other mechanisms Spasm of coronary arteries (Prinzmetal angina with normal coronary arteries) Spasm after nitroglycerin withdrawal Dissection of the aorta Dissection of the coronary artery
Emboli to Coronary Arteries
Infective endocarditis Nonbacterial thrombotic endocarditis Prolapse of the mitral valve Mural thrombus from the left atrium, left ventricle, or pulmonary veins Prosthetic valve emboli Cardiac myxoma Associated with cardiopulmonary bypass surgery and coronary arteriography Paradoxical emboli Papillary fibroelastoma of the aortic valve ("fixed embolus") Thrombi from intracardiac catheters or guidewires
Congenital Coronary Artery Anomalies
Anomalous origin of the left coronary from the pulmonary artery Left coronary artery from the anterior sinus of Valsalva Coronary arteriovenous and arteriocameral fistulas Coronary artery aneurysms
Myocardial Oxygen Demand-Supply Disproportion
Aortic stenosis, all forms Incomplete differentiation of the aortic valve Aortic insufficiency Carbon monoxide poisoning Thyrotoxicosis Prolonged hypotension Takotsubo cardiomyopathy
Hematologic (In Situ Thrombosis)
Polycythemia vera Thrombocytosis Disseminated intravascular coagulation Hypercoagulability, thrombosis, thrombocytopenic purpura
Miscellaneous
Cocaine abuse Myocardial contusion Myocardial infarction with normal coronary arteries Complication of cardiac catheterization

Modified from Cheitlin MD, McAllister HA, de Castro CM: Myocardial infarction without atherosclerosis. *JAMA* 231:951, 1975. Copyright 1975, American Medical Association.

FIGURE 51-2 A, Age- and sex-adjusted incidence rates of acute MI from 1999 to 2008. *I* bars represent 95% confidence intervals. **B**, Adjusted odds ratios are shown for 30-day mortality according to year after any MI (**B**, top), STEMI (**B**, middle), and NSTEMI (**B**, bottom). Models were adjusted for patient demographic characteristics, previous cardiovascular disease, cardiovascular risk factors, chronic lung disease, and systemic cancer. The reference year is 1999. See also Figure 53-2. (From Yeh RW, Sidney S, Chandra M, et al: Population trends in the incidence and outcomes of acute myocardial infarction. *N Engl J Med* 362:2155, 2010.)

When acute coronary atherothrombosis occurs, the resulting intracoronary thrombus may be partially obstructive, which generally leads to myocardial ischemia in the absence of ST-segment elevation, or be completely occlusive and cause transmural myocardial ischemia and STEMI. Before the fibrinolytic era, clinicians typically divided patients with MI into those in whom a Q wave developed on the ECG and those with non-Q-wave MI based on evolution of the ECG pattern over several days. The term *Q-wave infarction* was frequently considered to be virtually synonymous with *transmural infarction*, whereas *non-Q-wave infarctions* were often referred to as *subendocardial infarctions*. Contemporary studies using cardiac magnetic resonance (CMR) indicate that the development of a Q wave on the ECG is determined more by the size of the infarct than by the depth of mural involvement. Thus use of ACS as the more appropriate broad conceptual framework has replaced this terminology, anchored by the underlying unifying pathophysiology (see Fig. 51-1). Further classification of patients by the presence of ST-segment elevation (STEMI) or by its absence (non-ST-segment elevation ACS) rather than by the evolution of Q waves is preferable because immediate clinical decisions such as fibrinolysis or primary PCI depend on identification of diagnostic ST-segment elevation on the initial ECG.

Plaque (See also Chapter 41)

Atherosclerotic plaque begins early in life and grows slowly over decades.²⁵ Evidence of some atherosclerosis is almost ubiquitous in the modern world, yet most plaque remains asymptomatic throughout a lifetime. Other plaques may develop slowly and elicit stable symptoms. Plaque that precipitates an ACS event through the abrupt and catastrophic transition from a vulnerable, yet stable plaque to an unstable one characterized by plaque disruption or erosion and then subsequent overlying thrombosis is rare.^{23,26} Traditional risk factors and consequent chronic inflammation promote much of the development of atherosclerosis, although some patients have a systemic predisposition to plaque disruption that is independent of traditional risk factors. Plaque disruption exposes substances that promote platelet activation and aggregation, thrombin generation, and ultimately thrombus formation.^{23,26} The resultant thrombus interrupts blood flow and leads to an imbalance between oxygen supply and demand and, if this imbalance is severe and persistent, to myocardial necrosis (Fig. 51-3).

Composition of Plaque

The atherosclerotic plaque associated with total thrombotic occlusion of an epicardial coronary artery, located in infarct-related vessels, is generally more complex and irregular than the plaque in vessels not associated with STEMI.^{23,26} Histologic studies of these lesions often reveal plaque rupture or erosion (see Chapter 41). Thrombus composition may vary at different levels: white thrombi contain platelets, fibrin, or both, and red thrombi contain erythrocytes, fibrin, platelets, and leukocytes (see Chapter 82).

FIGURE 51-3 Schematic representation of the progression of myocardial necrosis after coronary artery occlusion. Necrosis begins in a small zone of the myocardium beneath the endocardial surface in the center of the ischemic zone. This entire region of myocardium (dashed outline) depends on the occluded vessel for perfusion and is the area at risk. A narrow zone of myocardium immediately beneath the endocardium is spared from necrosis because it can be oxygenated by diffusion from the ventricle. (From Schoen FJ: *The heart*. In Kumar V, Abbas AK, Fausto N [eds]: *Robbins & Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia, WB Saunders, 2009.)

Plaque Fissuring and Disruption

In autopsy studies, plaque rupture and plaque erosion are the most common underlying causes of MI and sudden cardiac death. Plaque rupture is present in almost three quarters of cases and is more prevalent in men. Plaque erosion is more frequent in women younger than 50 years, although the prevalence of rupture increases as women age.²³ Atherosclerotic plaque considered prone to disruption or erosion is most likely plaque that has evolved to a morphology that includes a necrotic core filled with lipids and inflammatory cells and covered by a thin and inflamed fibrous cap. A prospective study of 697 patients with ACS who underwent three-vessel coronary angiography and gray-scale radiofrequency intravascular ultrasonographic imaging after PCI found that three lesion characteristics—lipid burden greater than 70%, thin-cap fibroatheroma morphology, and a minimal luminal area of 4.0 mm² or smaller—were independent correlates of future atherosclerotic events (Fig. 51-4).²⁷ Other morphologic characteristics associated with rupture-prone plaque include expansive remodeling that minimizes luminal obstruction (mild stenosis by angiography), neovascularization (angiogenesis), plaque hemorrhage, adventitial inflammation, and a “spotty” pattern of calcification.²³

Inflammation stimulates the overexpression of enzymes that degrade components of the plaque’s extracellular matrix.^{23,26} Activated macrophages and mast cells, abundant at the site of plaque disruption in patients who die of STEMI, can elaborate these proteinases. In addition to these structural aspects of vulnerable or high-risk plaque, stress induced by intraluminal pressure, coronary vasomotor tone, tachycardia (cyclical stretching and compression), and disruption of microvessels combines to produce plaque disruption at the margin of the fibrous cap near an adjacent, less involved segment of the coronary artery wall (shoulder region of the plaque).²⁵ Several key

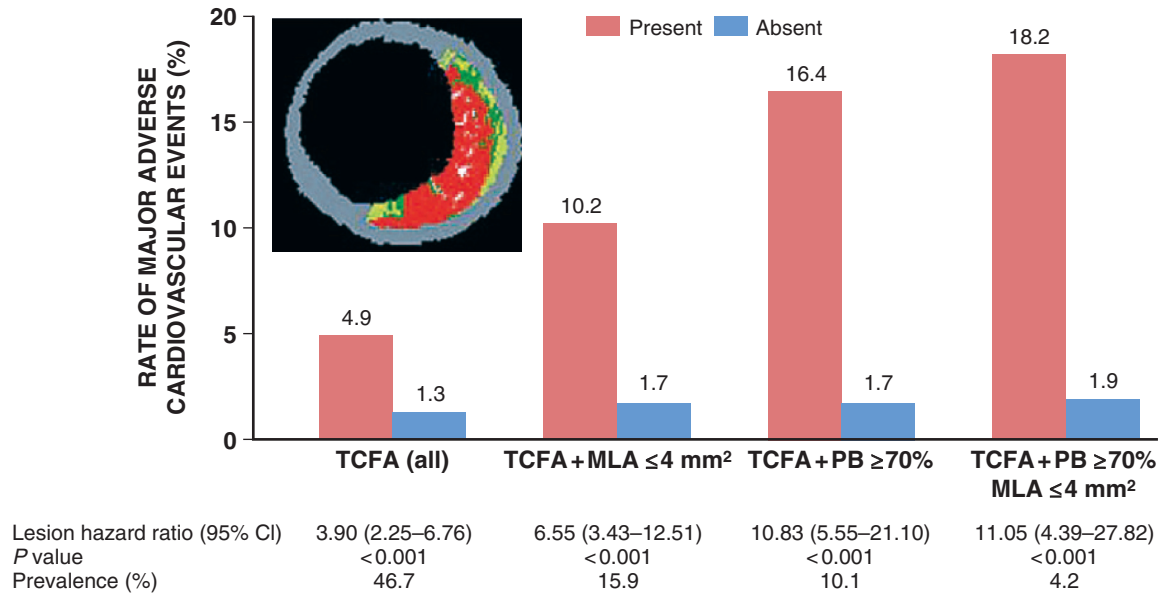

FIGURE 51-4 Comparison of cardiovascular event rates for lesions that were and those that were not thin-cap fibroatheromas (TCFAs). This figure shows the event rates associated with 595 nonculprit lesions that were characterized as TCFAs and 2114 that were not by means of gray-scale radiofrequency intravascular ultrasonographic imaging according to minimal luminal area (MLA) and plaque burden (PB). Lesions that had a larger plaque burden, signifying greater atherosclerotic content, and smaller lumen were at greatest risk for subsequently triggering an acute coronary event. The *inserted image* is an example of a TCFA imaged by radiofrequency ultrasonography. Red indicates necrotic core, dark green indicates fibrous tissue, white indicates confluent dense calcium, and light green indicates fibrofatty tissue. CI = confidence interval. (From Stone GW, Maehara A, Lansky AJ, et al: A prospective natural-history study of coronary atherosclerosis. *N Engl J Med* 364:226, 2011.)

physiologic variables—such as systolic blood pressure, heart rate, blood viscosity, endogenous tissue plasminogen activator (t-PA) activity, plasminogen activator inhibitor-1 (PAI-1) levels, plasma cortisol levels, and plasma epinephrine levels—exhibit circadian and seasonal variations and increase at times of stress. These factors act in concert to heighten the propensity for plaque disruption and coronary thrombosis, with the result that STEMI clusters in the early morning hours, especially in the winter and after natural disasters.²⁸⁻³⁰

Acute Coronary Syndromes

Plaque disruption exposes thrombogenic substances that may produce an extensive thrombus in the infarct-related artery (see Fig. 51-1). An adequate collateral network that prevents necrosis from occurring can result in clinically silent episodes of coronary occlusion; in addition, many plaque ruptures are asymptomatic if the thrombosis is not occlusive. Characteristically, completely occlusive thrombi lead to transmural injury to the ventricular wall in the myocardial bed subtended by the affected coronary artery (Fig. 51-5; see also Figs. 51-1 and 51-3). Infarction alters the sequence of depolarization ultimately reflected as changes in the QRS.³¹ The most characteristic change in the QRS that develops in most patients with STEMI is the evolution of Q waves in leads overlying the infarct zone (see Figs. 51-1 and 51-5).³¹ In a minority of patients with ST elevation, no Q waves develop but other abnormalities in the QRS complex occur frequently, such as diminution in R wave height and notching or splintering of the QRS (see Chapter 12). Patients who have ischemic symptoms without ST elevation are initially diagnosed as suffering either from unstable angina or, with evidence of myocardial necrosis, from NSTEMI (see Fig. 51-1).

Patients with persistent ST-segment elevation are candidates for reperfusion therapy (either pharmacologic or catheter based) to restore flow in the occluded epicardial infarct-related artery (see Chapter 52).¹⁰ ACS patients without ST-segment elevation are not candidates for pharmacologic reperfusion but should receive anti-ischemic therapy, followed in most cases by PCI (see Chapter 53). Thus the 12-lead ECG remains at the center of the decision pathway for the management of patients with ACS to distinguish between those with ST elevation and those without it (see Figs. 51-1 and Fig. 55-5).³²

Heart Muscle

The cellular effects of ischemia commence within seconds of the onset of hypoxia with the loss of adenosine triphosphate (ATP) production. Myocardial relaxation-contraction is compromised, and irreversible cell injury begins within as early as 20 minutes. Necrosis is usually complete in 6 hours unless reperfusion occurs or an extensive collateral circulation is present (Fig. 51-6).

Gross Pathologic Findings. On gross inspection, MI falls into two major types: transmural infarcts, in which myocardial necrosis involves the full thickness (or almost full thickness) of the ventricular wall, and subendocardial (nontransmural) infarcts, in which the necrosis involves the subendocardium, the intramural myocardium, or both without extending all the way through the ventricular wall to the epicardium (Fig. 51-7).

Occlusive coronary thrombosis appears to be far more common when the infarction is transmural and localized to the distribution of a single coronary artery (see Fig. 51-5). Nontransmural infarctions, however, frequently occur in the presence of severely narrowed but still patent coronary arteries or when the infarcted region has sufficient collateral circulation. Patchy nontransmural infarction may arise secondary to fibrinolysis or PCI of an originally occlusive thrombus with restoration of blood flow *before* the wave front of necrosis has extended from the subendocardium across the full thickness of the ventricular wall (see Fig. 51-3).

Histologic and Ultrastructural Findings. Gross alterations in the myocardium are difficult to identify until at least 6 to 12 hours has elapsed following the onset of necrosis (Fig. 51-8), but a variety of histochemical stains can identify zones of necrosis after only 2 to 3 hours (Fig. 51-9).³³ Subsequently, the infarcted myocardium undergoes a sequence of gross pathologic changes (Fig. 51-10; see also Fig. 51-8).³⁴ Within hours of death from MI, the presence of an infarct can often be detected by immersing slices of myocardium in triphenyltetrazolium chloride, which turns noninfarcted myocardium a brick red color while the infarcted area remains unstained (see Fig. 51-7).

Microscopic Findings. Histologic evaluation of MI reveals various stages of the healing process (see Figs. 51-8 to 51-10). In experimental infarction, the earliest ultrastructural changes in cardiac muscle following ligation of a coronary artery, noted within 20 minutes, consist of a reduction in the size and number of glycogen granules; intracellular edema; and swelling and distortion of the transverse tubular system, sarcoplasmic reticulum, and mitochondria (see Fig. 51-8).³⁵

Location of zones of necrosis following occlusion of major epicardial coronary arteries

FIGURE 51-5 Correlation of sites of coronary occlusion, zones of necrosis, and abnormalities on the ECG. At the top is a schematic diagram of the heart with the location of the major epicardial coronary arteries. Immediately below, another schematic diagram depicts a short-axis view of the left and right ventricles and approximate location of the left anterior descending (LAD), left circumflex (LCX), and right coronary artery (RCA); the latter gives rise to the posterior descending artery (PDA) in most patients. The middle of the figure shows the location of the zones of necrosis following occlusion of a major epicardial coronary artery. Identification of the infarct artery from the 12-lead ECG is shown at the bottom. The 17 myocardial segments in a polar map format (A) are shown with superimposition of the arterial supply provided by the LAD artery (B), RCA (C), and LCX artery (D). E, Position of the standard ECG leads relative to the polar map. The infarct artery can be deduced by identifying the leads that show ST elevation and referencing that information to A to D. For example, ST elevation seen most prominently in the leads overlying segments 1, 2, 7, 8, 13, 14, and 17 indicates that the LAD is the infarct artery. D₁ = first diagonal; OM = obtuse marginal; PB = posterobasal; PD = posterior descending; PL = posterolateral; S₁ = first septal. (From Bayes-de-Luna A, Wagner G, Birnbaum Y, et al: A new terminology for the left ventricular walls and location of myocardial infarcts that present Q wave based on the standard of cardiac magnetic resonance imaging. *Circulation* 114:1755, 2006.)

FIGURE 51-6 Schematic drawing of the coronary artery circulation without (**A**) and with (**B**) interarterial anastomoses between the right coronary artery and the occluded left anterior descending artery (occluded downstream of the third diagonal branch). **A**, The gray area indicates the ischemic area at risk for MI (finally corresponding to infarct size) in the case of left anterior descending artery occlusion and in the absence of collaterals. **B**, The area at risk for MI is equal to zero because of the extended collaterals. (From Traupe T, Gloekler S, de Marchi SF, et al: Assessment of the human coronary collateral circulation. *Circulation* 122:1210, 2010.)

FIGURE 51-7 Top, Acute MI, predominantly of the posterolateral left ventricle, demonstrated histochemically by lack of staining with triphenyltetrazolium chloride in areas of necrosis. The staining defect is caused by leakage of the enzyme following cell death. The myocardial hemorrhage at one edge of the infarct was associated with cardiac rupture, and the anterior scar (lower left) was indicative of an old infarct. The specimen was oriented with the posterior wall at the top. Bottom, The early tissue response to the infarction process involves a mixture of bland necrosis, inflammation, and hemorrhage. (From Schoen FJ: *The heart*. In Kumar V, Abbas AK, Fausto N [eds]: *Robbins & Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia, WB Saunders, 2009.)

These early changes are reversible. Changes after 60 minutes of occlusion include myocyte swelling, swelling and internal disruption of mitochondria, development of amorphous, flocculent aggregation and margination of nuclear chromatin, and relaxation of myofibrils. After 20 minutes to 2 hours of ischemia, the changes in some cells become irreversible and progression of these alterations occurs.³⁴

Patterns of Myocardial Necrosis

Coagulation Necrosis. Coagulation necrosis results from severe, persistent ischemia and is usually present in the central region of infarcts; it causes arrest of muscle cells in the relaxed state and passive stretching of ischemic muscle cells. The tissue exhibits stretched myofibrils, many cells with pyknotic nuclei, congested microvessels, and phagocytosis of necrotic muscle cells (see Fig. 51-8). Mitochondrial damage with prominent amorphous (flocculent) densities occurs, but no calcification is evident.

Necrosis with Contraction Bands. This form of myocardial necrosis, also termed *contraction band necrosis* or *coagulative myocytolysis*, results primarily from severe ischemia followed by reflow.³⁴ It is characterized by hypercontracted myofibrils with contraction bands and mitochondrial damage, frequently with calcification, marked vascular congestion, and healing by lysis of muscle cells. Necrosis with contraction bands is caused by increased influx of Ca^{2+} into dying cells, which results in the arrest of cells in the contracted state in the periphery of large infarcts and, to a greater extent, in nontransmural than in transmural infarcts. The entire infarct may show this form of necrosis after reperfusion (see Fig. 51-9).

Myocytolysis. Ischemia without necrosis generally causes no acute changes visible on light microscopy, but severe prolonged ischemia can result in myocyte vacuolization, often termed *myocytolysis*. Prolonged severe ischemia, which is potentially reversible, causes cloudy swelling, as well as hydropic, vascular, and fatty degeneration.

Apoptosis. An additional pathway of myocyte death involves apoptosis, or programmed cell death. In contrast to coagulation necrosis, myocytes undergoing apoptosis exhibit shrinkage of cells, fragmentation of DNA, and phagocytosis but without the usual cellular infiltrate indicative of inflammation.³⁴ The role of apoptosis in the setting of MI is less well understood than that of classic coagulation necrosis. Apoptosis may occur shortly after the onset of myocardial ischemia, but its major impact appears to be on late myocyte loss and ventricular remodeling after MI.³⁶

Current Concepts of the Cellular Events During Myocardial Infarction and Healing

Classic studies defined the sequence of cellular events that occur during human MI by careful histologic studies.³⁷ Accumulation of granulocytes characterized the first days following MI. After the first days, mononuclear phagocytes accumulated in the infarct in tissue. Finally, granulation tissue characterized by neovascularization and accumulation of extracellular matrix (fibrosis) followed. Recent experimental work in mice has revealed a sequence of accumulation of subpopulations of mononuclear phagocytes.³⁸ The first wave, occurring about days 1 to 3 following coronary ligation, consists of a proinflammatory subset of monocytes characterized by high proteolytic and phagocytic capacity and elaboration of proinflammatory cytokines. During a later phase (days 3 to 7), less inflammatory monocytes predominate and produce the angiogenic mediator vascular endothelial growth factor (VEGF) and the fibrogenic mediator transforming growth factor-beta (TGF- β). This highly orchestrated sequential recruitment of subpopulations of monocytes probably plays an important role in myocardial healing. The first wave of proinflammatory and phagocytically active mononuclear cells constitutes a “cleanup

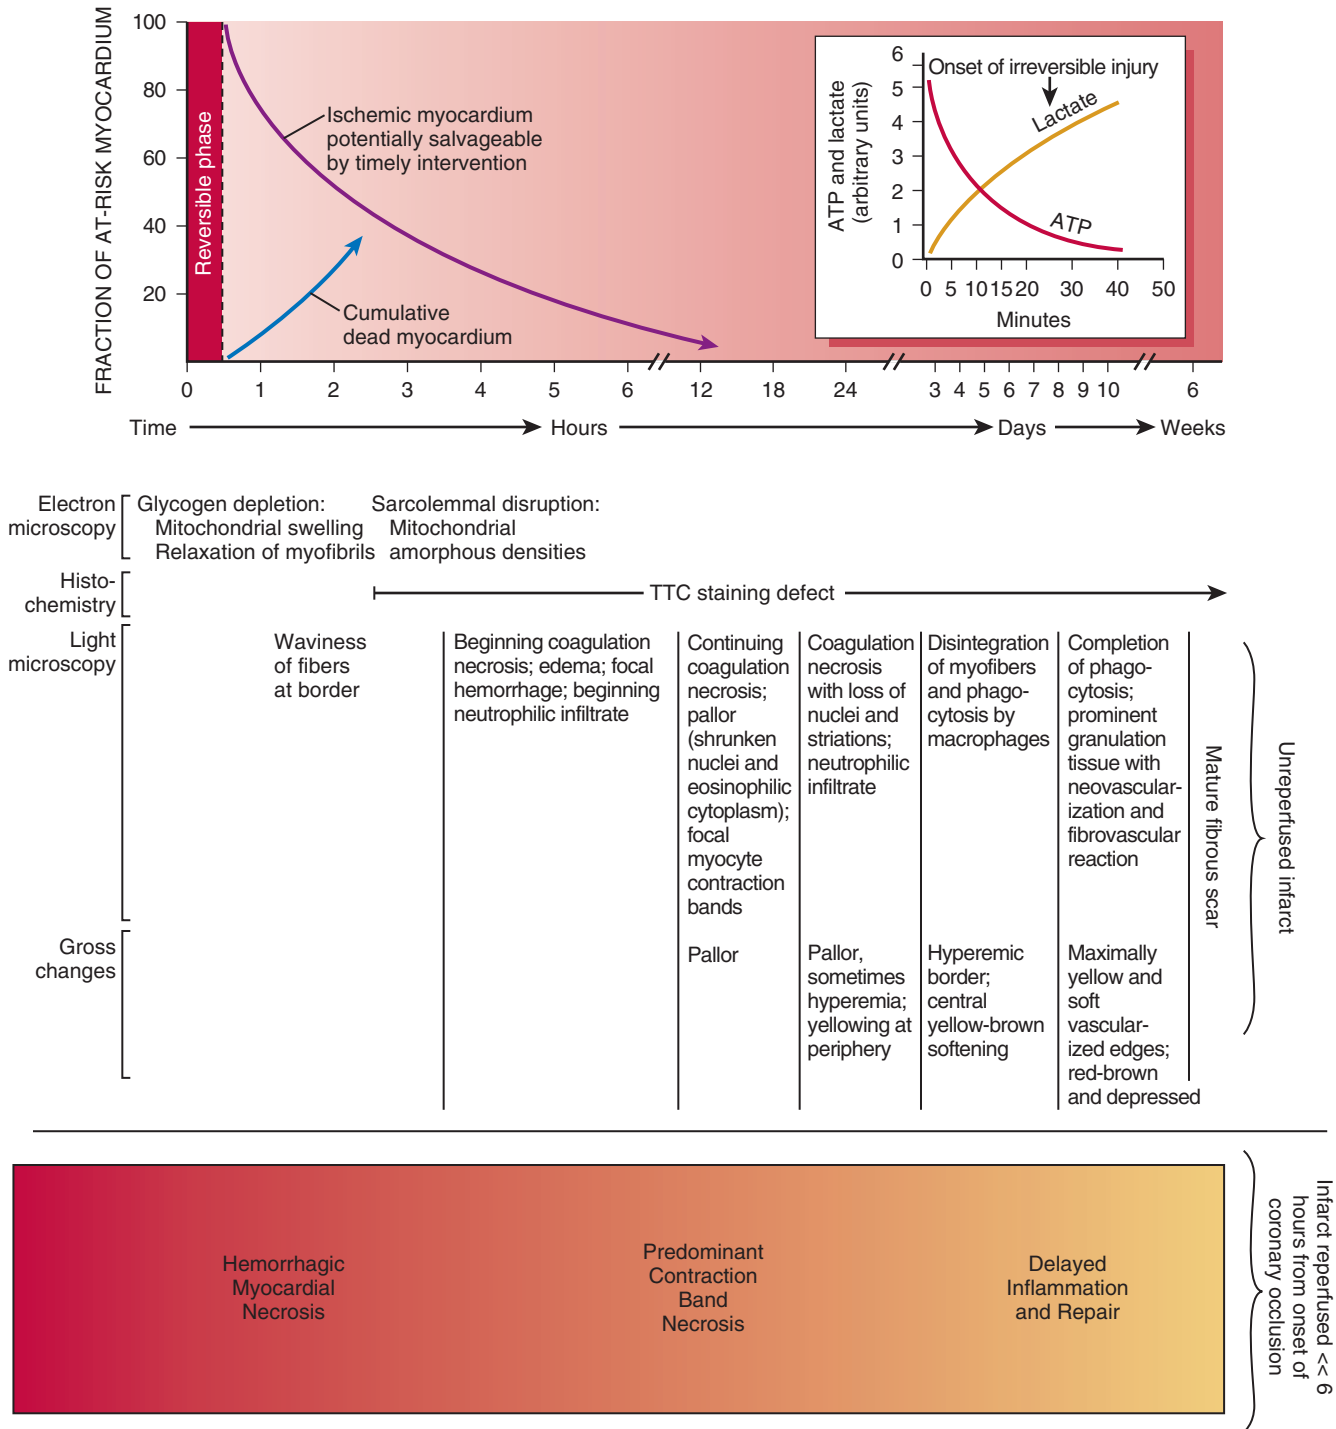

FIGURE 51-8 Temporal sequence of early biochemical, ultrastructural, histochemical, and histologic findings after the onset of MI. **Top**, Schematics of the time frames for early and late reperfusion of the myocardium supplied by an occluded coronary artery. For approximately 30 minutes after the onset of even the most severe ischemia, myocardial injury is potentially reversible; after this point, progressive loss of viability occurs and is complete by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early, with progressively smaller benefits occurring as reperfusion is delayed. Note the alterations in the temporal sequence in the reperfused infarct. The pattern of pathologic findings following reperfusion varies depending on the timing of reperfusion, previous infarction, and collateral flow. TTC = triphenyltetrazolium chloride. (From Schoen FJ: *The heart*. In Kumar V, Abbas AK, Fausto N [eds]: *Robbins & Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia, WB Saunders, 2009.)

crew" that clears necrotic debris and paves the way for the second wave of less inflammatory monocytes, which contribute to healing by promoting the formation of granulation tissue.

Modification of Pathologic Changes by Reperfusion

When reperfusion of myocardium undergoing the evolutionary changes from ischemia to infarction occurs sufficiently early (i.e.,

within 15 to 20 minutes), it can successfully prevent necrosis from developing. Beyond this early stage, the number of salvaged myocytes—and therefore the amount of salvaged myocardial tissue (area of necrosis/area at risk)—is directly related to the length of time of total coronary artery occlusion, the level of myocardial oxygen consumption, and collateral blood flow (**Fig. 51-11**). Reperfused infarcts typically show a mixture of necrosis, hemorrhage within zones

FIGURE 51-9 Microscopic features of MI. **A**, One-day-old infarct showing coagulative necrosis, wavy fibers with elongation, and narrowing as compared with adjacent normal fibers (*lower right*). Widened spaces between the dead fibers contain edema fluid and scattered neutrophils. **B**, Dense polymorphonuclear leukocytic infiltrate in an area of acute MI of 3 to 4 days' duration. **C**, Almost complete removal of necrotic myocytes by phagocytosis (≈ 7 to 10 days). **D**, Granulation tissue with a rich vascular network and early collagen deposition, approximately 3 weeks after infarction. **E**, Well-healed myocardial infarct with replacement of necrotic fibers by dense collagenous scar. A few residual cardiac muscle cells are present. (In **D** and **E**, collagen is highlighted as blue in this Masson trichrome stain.) **F**, Myocardial necrosis with hemorrhage and contraction bands, visible as dark bands spanning some myofibers (*arrows*). This is the characteristic appearance of markedly ischemic myocardium that has been reperfused. (From Schoen FJ: *The heart*. In Kumar V, Abbas AK, Fausto N [eds]: *Robbins & Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia, WB Saunders, 2009.)

of irreversibly injured myocytes, coagulative necrosis with contraction bands, and distorted architecture of cells in the reperfused zone (**Fig. 51-12**). Reperfusion of infarcted myocardium accelerates the washout of leaked intracellular proteins, thereby producing an exaggerated and early peak value of substances such as the MB fraction of creatine kinase (CK-MB) and cardiac-specific troponin T and I (see below).³⁹

Coronary Anatomy and Location of Infarction

Angiographic studies performed in the earliest hours of STEMI have revealed an approximately 90% incidence of total occlusion of the infarct-related vessel. Recanalization as a result of spontaneous thrombolysis diminishes angiographic total occlusion in the period following the onset of MI. Pharmacologic fibrinolysis and PCI markedly increase the proportion of patients with a patent infarct-related artery early after STEMI.

A STEMI with transmural necrosis typically occurs distal to an acutely totally occluded coronary artery with thrombus superimposed on a ruptured plaque (see **Fig. 51-5**). Yet chronic total occlusion of a coronary artery does not always cause MI. Collateral blood flow and other factors such as the level of myocardial metabolism, the presence and location of stenoses in other coronary arteries, the rate

of development of the obstruction, and the quantity of myocardium supplied by the obstructed vessel all influence the viability of myocardial cells distal to the occlusion. In many series of patients studied at necropsy or by coronary arteriography, a small number (5%) of those with STEMI have normal coronary vessels. An embolus that has lysed, a transiently occlusive platelet aggregate, or a prolonged episode of severe coronary spasm may cause the infarct in these patients.

Studies of patients in whom STEMI ultimately develops after having undergone coronary angiography at some time before its occurrence have helped clarify the coronary anatomy before infarction. Although high-grade stenoses, when present, more frequently lead to STEMI than do less severe lesions, most occlusions occur in vessels with a previously identified stenosis of less than 50% on angiograms performed months to years earlier.²⁷ This finding supports the concept that STEMI results from sudden thrombotic occlusion at the site of rupture of previously nonobstructive but lipid-rich plaque. When collateral vessels perfuse an area of the ventricle, an infarct may occur at a distance from a coronary occlusion. For example, following gradual obliteration of the lumen of the right coronary artery, collateral vessels arising from the left anterior descending coronary artery

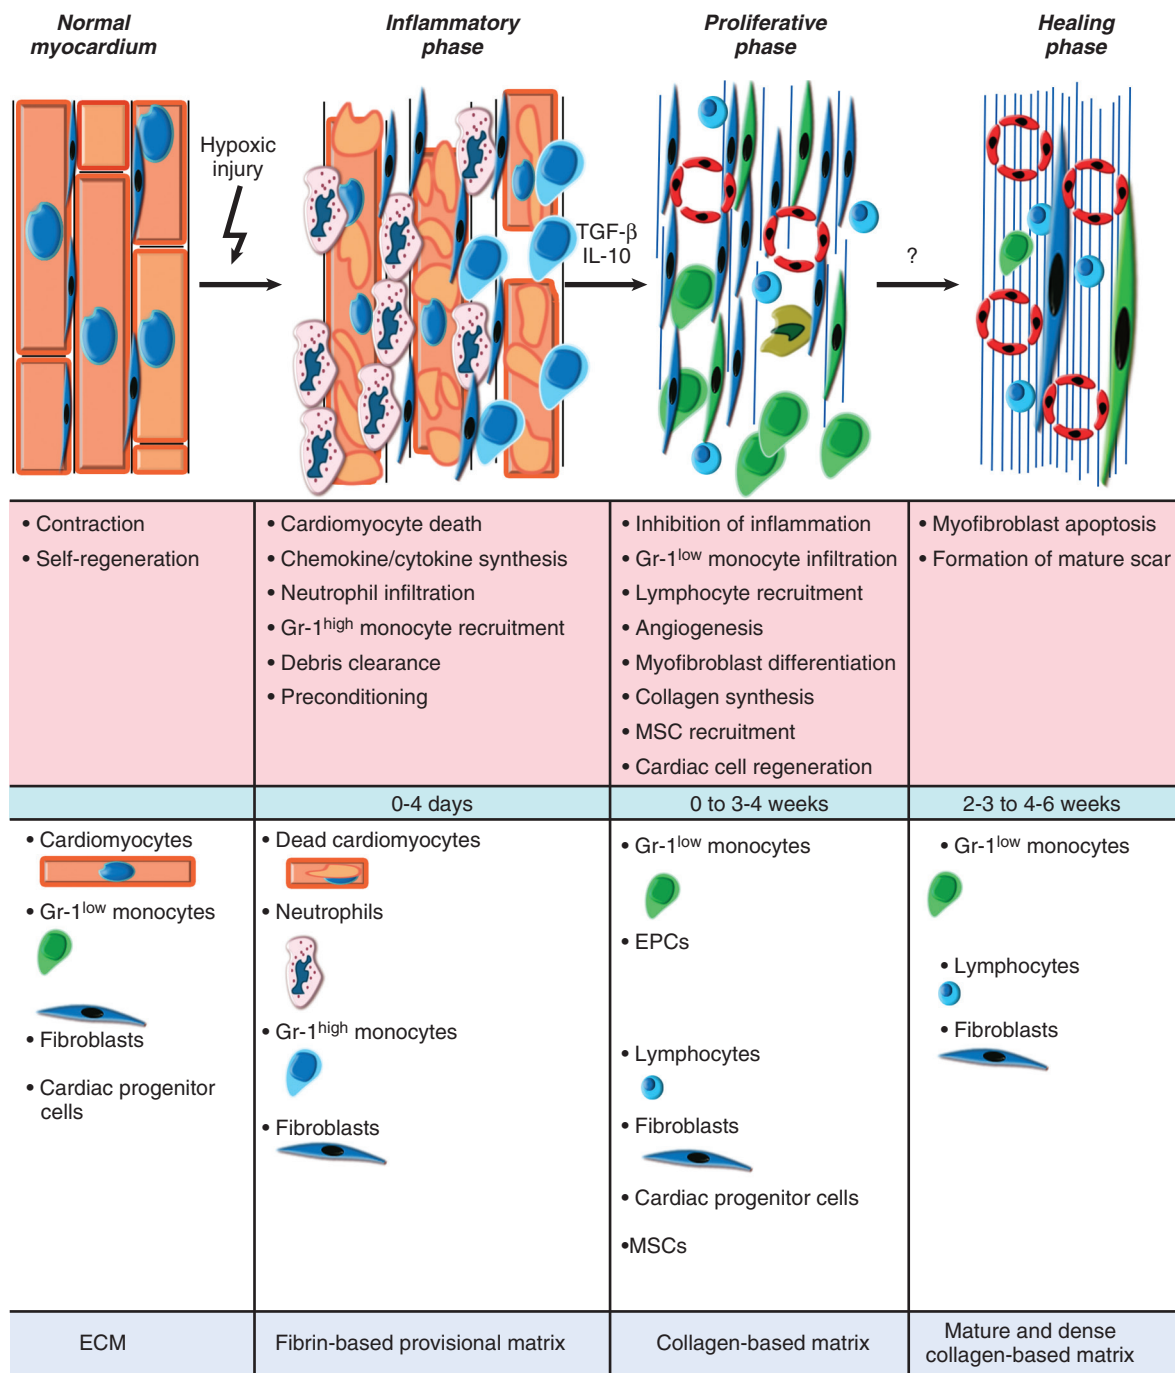

FIGURE 51-10 Healing after MI involves three overlapping phases: inflammatory, proliferative, and healing. Each is characterized by specific events and processes (red boxes) mediated by different cells controlled by specific chemokines. TGF- β and IL-10 signal transition from the inflammatory to proliferative phase. Extracellular matrix (ECM) evolves to mature scar (dark blue in top right), which ensures the stability and function of the heart. GR-1^{high} monocytes induce inflammation and phagocytosis whereas GR-1^{low} monocytes facilitate healing. EPCs = endothelial progenitor cells; IL = interleukin; MSC = mesenchymal stem cell; TGF = transforming growth factor. (From Liehn EA, Postea O, Curaj A, Marx N: Repair after myocardial infarction, between fantasy and reality: The role of chemokines. *J Am Coll Cardiol* 2011;58:2357, 2011.)

can keep the inferior wall of the left ventricle viable. Later, an occlusion of the left anterior descending artery may cause infarction of the diaphragmatic wall.

Right Ventricular Infarction

Approximately 50% of patients with inferior infarction have some involvement of the right ventricle.⁴⁰ Among these patients, right ventricular (RV) infarction occurs exclusively in those with transmural infarction of the inferoposterior wall and the posterior portion of the septum. RV infarction almost invariably develops in association with infarction of the adjacent septum and inferior left ventricular (LV) walls, but isolated infarction of the right ventricle is seen in just 3%

to 5% of autopsy-proven cases of MI. RV infarction occurs less commonly than would be anticipated from the frequency of atherosclerotic lesions involving the right coronary artery. The right ventricle can sustain long periods of ischemia but still demonstrate excellent recovery of contractile function after reperfusion.

Atrial Infarction

This type of infarction occurs in up to 10% of patients with STEMI if PR-segment displacement is used as the criterion. Although isolated atrial infarction is observed in only 3.5% of patients with STEMI at autopsy, it often occurs in conjunction with ventricular infarction and can cause rupture of the atrial wall.⁴¹ This type of infarction is more

FIGURE 51-11 Consequences of reperfusion at various times after coronary occlusion. In this example the mid-portion of the left anterior descending coronary artery is occluded and a large zone of ischemic myocardium develops—the “area at risk.” Reperfusion in less than 20 minutes does not result in permanent loss of tissue, but there may be a period of contractile dysfunction of the reperfused myocardium—a condition referred to as “stunning.” Later reperfusion results in hemorrhagic necrosis with contraction bands. Permanent occlusion results in necrosis of myocardium. (From Schoen FJ: *The heart*. In Kumar V, Abbas AK, Fausto N [eds]: *Robbins & Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia, WB Saunders, 2009.)

common on the right side than on the left side, occurs more frequently in the atrial appendages than in the lateral or posterior walls of the atrium, and can result in thrombus formation. Atrial infarction is frequently accompanied by atrial arrhythmias and has been linked to reduced secretion of atrial natriuretic peptide and to a low-cardiac output syndrome when RV infarction coexists.

Collateral Circulation in Acute Myocardial Infarction (See Chapter 49)

The coronary collateral circulation is particularly well developed in patients with coronary occlusive disease, especially with reduction of the luminal cross-sectional area by more than 75% in one or more major vessels; in patients with chronic hypoxia, as occurs in cases of severe anemia, chronic obstructive pulmonary disease, and cyanotic congenital heart disease; and in patients with LV hypertrophy (see Fig. 51-6).⁴²

The magnitude of coronary collateral flow is a principal determinant of infarct size. Indeed, patients with abundant collateral vessels commonly have totally occluded coronary arteries without evidence of infarction in the distribution of that artery; thus survival of myocardium distal to such occlusions depends largely on collateral blood flow. Even if the collateral perfusion existing at the time of coronary occlusion does not prevent infarction, it may still exert a beneficial effect by preventing the formation of LV aneurysms. The presence of a high-grade stenosis (90%), possibly with periods of intermittent total occlusion, probably permits the development of collateral vessels that remain only as potential conduits until a total occlusion occurs or recurs. Total occlusion then brings these channels into full operation. Patients with angiographic evidence of collateral formation have improved angiographic and clinical outcomes after MI.

Nonatherosclerotic Causes of Acute Myocardial Infarction

Numerous pathologic processes other than atherosclerosis can involve the coronary arteries and result in STEMI (see Table 51-3).

For example, coronary arterial occlusions can result from embolization of a coronary artery. The causes of coronary embolism are numerous: infective endocarditis and nonbacterial thrombotic endocarditis (see Chapter 64), mural thrombi, prosthetic valves, neoplasms, air introduced at the time of cardiac surgery, and calcium deposits from manipulation of calcified valves at surgery. In situ thrombosis of coronary arteries can occur secondary to chest wall trauma (see Chapter 72).

A variety of inflammatory processes can cause coronary artery abnormalities, some of which mimic atherosclerotic disease and may predispose to true atherosclerosis. Epidemiologic evidence suggests that viral infections, particularly with Cocksackie B virus, may uncommonly cause MI. Viral illnesses occasionally precede MI in young persons who are later shown to have normal coronary arteries.

Syphilitic aortitis can produce marked narrowing or occlusion of one or both coronary ostia, whereas Takayasu arteritis can result in obstruction of the coronary arteries. Necrotizing arteritis, polyarteritis nodosa, mucocutaneous lymph node syndrome (Kawasaki disease), systemic lupus erythematosus (see Chapter 84), and giant cell arteritis can cause coronary occlusion. Therapeutic levels of mediastinal radiation can

result in coronary arteriosclerosis⁴³ with subsequent infarction. MI can also result from coronary arterial involvement in patients with amyloidosis (see Chapter 65), Hurler syndrome, pseudoxanthoma elasticum, and homocystinuria. Cocaine can cause MI in patients with normal coronary arteries, preexisting MI, documented coronary artery disease, or coronary artery spasm (see Chapter 68).

Myocardial Infarction with Angiographically Normal Coronary Vessels

Patients with STEMI and normal coronary arteries tend to be young with relatively few coronary risk factors except that they often have a history of cigarette smoking (Table 51-4). Usually, they have no history of angina pectoris before the infarction. These patients do not generally have a prodrome before infarction, but the clinical, laboratory, and electrocardiographic features of STEMI otherwise resemble those present in the overwhelming majority of patients with STEMI who have classic obstructive atherosclerotic coronary artery disease.

Patients who recover frequently have areas of localized dyskinesia and hypokinesia identified at LV angiography. Many of these cases result from coronary artery spasm and/or thrombosis, perhaps with underlying endothelial dysfunction or plaque not apparent on coronary angiography. The transient LV apical ballooning syndrome (takotsubo cardiomyopathy) is characterized by transient wall motion abnormalities involving the LV apex and midventricle (Fig. 51-13). This syndrome occurs in the absence of obstructive epicardial coronary disease and can mimic STEMI.^{44,45} Typically, an episode of psychological stress precedes the development of takotsubo cardiomyopathy. Initial ECGs demonstrate significant and often diffuse ST-segment elevations that when coupled with the typical (frequently severe) chest discomfort, prompts the appropriate immediate referral for coronary angiography. The cause is not clear, but catecholamine-mediated myocardial stunning and microvascular dysfunction play important roles.⁴⁶

Additional suggested causes include (1) coronary emboli (perhaps from a small mural thrombus, a prolapsed mitral valve, or a myxoma);

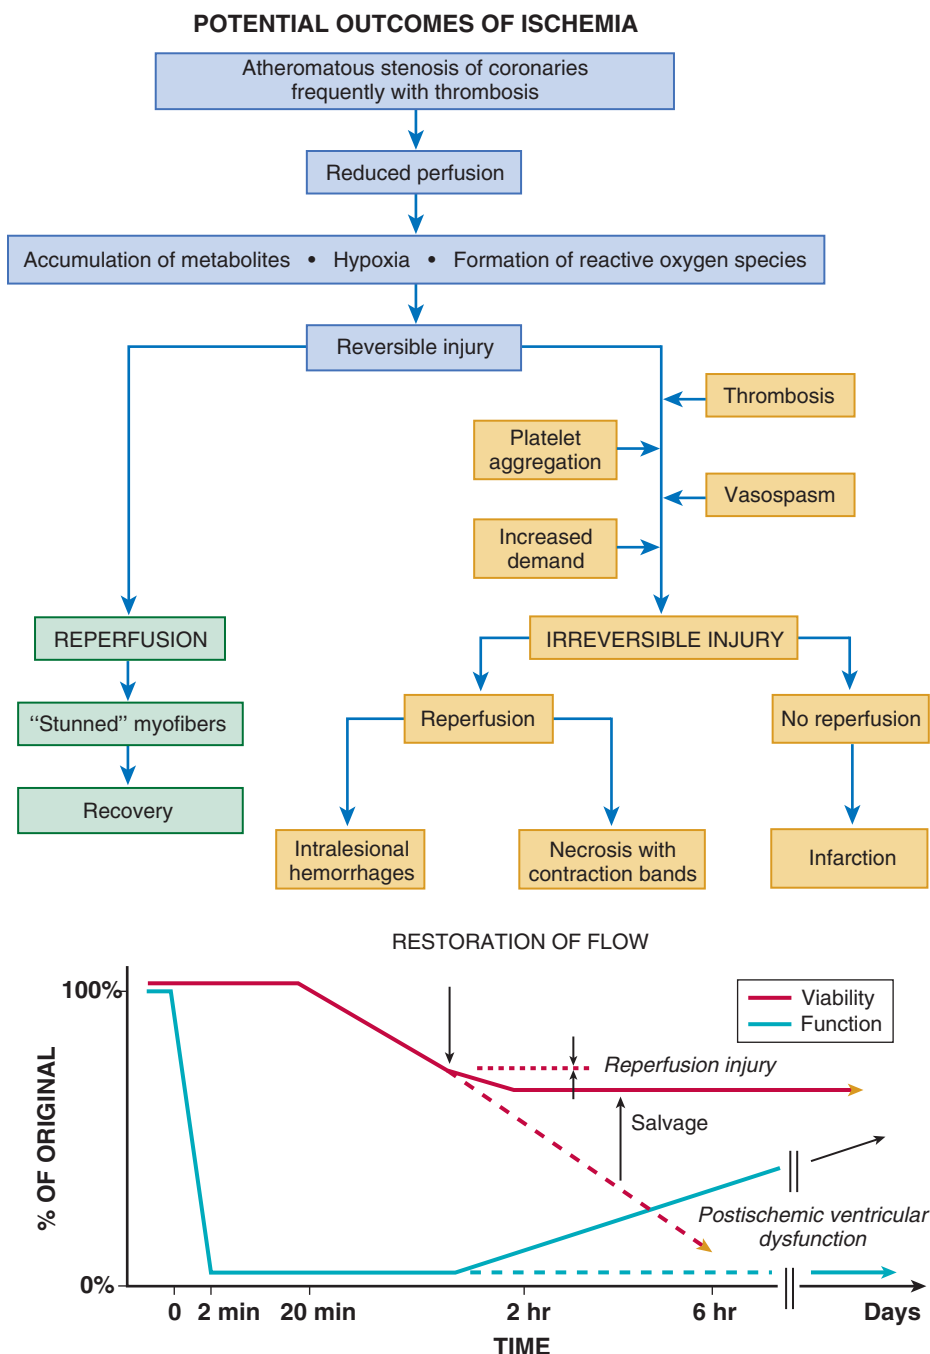

FIGURE 51-12 Several potential outcomes of reversible and irreversible ischemic injury to the myocardium. The schematic diagram at the bottom depicts the timing of changes in function and viability. A key point is that although function drops dramatically after coronary occlusion, the tissue is still viable for a period. This is the basis for early aggressive efforts at reperfusion of patients with STEMI. (From Schoen FJ: *The heart*. In Kumar V, Abbas AK, Fausto N [eds]: *Robbins & Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia, WB Saunders, 2009.)

(2) coronary artery disease in vessels too small to be visualized on coronary arteriography or coronary arterial thrombosis with subsequent recanalization; (3) a hematologic disorder (polycythemia vera, cyanotic heart disease with polycythemia, sickle cell anemia, disseminated intravascular coagulation, thrombocytosis, and thrombotic thrombocytopenic purpura) causing in situ thrombosis in the presence of normal coronary arteries; (4) augmented oxygen demand (e.g., thyrotoxicosis, amphetamine use); (5) hypotension secondary to sepsis, blood loss, or pharmacologic agents; and (6) anatomic variations such as anomalous origin of a coronary artery (see Chapter 20), coronary arteriovenous fistula, or a myocardial bridge.

Prognosis

The long-term outlook for patients who have survived STEMI with angiographically normal coronary vessels appears to be brighter than for those with STEMI and obstructive coronary artery disease.⁴⁵ After recovery from the initial infarct, recurrent infarction, heart failure, and death are unusual in patients with normal coronary arteries. Indeed, most of these patients have normal finding on the exercise ECG, and very few develop angina pectoris.

PATHOPHYSIOLOGY

Left Ventricular Function

Systolic Function

On interruption of antegrade flow in an epicardial coronary artery, the zone of myocardium supplied by that vessel immediately loses its ability to shorten and perform contractile work (see Fig. 51-12). Four abnormal contraction patterns develop in sequence: (1) dyssynchrony, or dissociation of the time course of contraction of adjacent segments; (2) hypokinesis, or a reduction in the extent of shortening; (3) akinesis, or cessation of shortening; and (4) dyskinesis, paradoxical expansion, and systolic bulging. Hyperkinesis of the remaining normal myocardium initially accompanies dysfunction of the infarct. The early hyperkinesis of the noninfarcted zones probably results from acute compensation, including increased activity of the sympathetic nervous system and the Frank-Starling mechanism. A portion of this compensatory hyperkinesis is ineffective work because contraction of the noninfarcted segments of myocardium causes dyskinesis of the infarct zone. The increased motion of the noninfarcted region subsides within 2 weeks of infarction, during which time some degree of recovery often occurs in the infarct region as well, particularly if reperfusion of the infarcted area occurs and myocardial stunning diminishes.

Patients with STEMI also often have reduced myocardial contractile function in noninfarcted zones. This finding may result from previous obstruction of the coronary artery supplying the noninfarcted region of the ventricle and loss of collaterals from the freshly occluded infarct-related vessel, a condition termed *ischemia at a distance*. Conversely, the development of collaterals before STEMI occurs may allow greater

preservation of regional systolic function in an area of distribution of the occluded artery and improvement in the LV ejection fraction early after infarction (see Fig. 51-6).⁴²

If a sufficient quantity of myocardium undergoes ischemic injury (see Fig. 51-12), LV pump function becomes depressed; cardiac output, stroke volume, blood pressure, and peak dp/dt decline; and end-systolic volume increases. The degree to which end-systolic volume increases is perhaps the most powerful hemodynamic predictor of mortality following STEMI.⁴⁷ Paradoxical systolic expansion of an area of ventricular myocardium further decreases LV stroke volume.⁴⁸ As necrotic myocytes slip past each other, the infarct zone thins and elongates, especially in patients with large anterior infarcts, thereby

TABLE 51-4 Causes of Myocardial Injury

Injury Related to Primary Myocardial Ischemia
Plaque rupture Intraluminal coronary artery thrombus formation
Injury Related to the Supply-Demand Imbalance of Myocardial Ischemia
Tachyarrhythmias/bradyarrhythmias Aortic dissection or severe aortic valve disease Hypertrophic cardiomyopathy Cardiogenic, hypovolemic, or septic shock Severe respiratory failure Severe anemia Hypertension with or without LV hypertrophy Coronary spasm Coronary embolism or vasculitis Coronary endothelial dysfunction without significant coronary artery disease
Injury Not Related to Myocardial Ischemia
Cardiac contusion, surgery, ablation, pacing, or defibrillator shocks Rhabdomyolysis with cardiac involvement Myocarditis Cardiotoxic agents (e.g., anthracyclines, trastuzumab [Herceptin])
Multifactorial or Indeterminate Myocardial Injury
Heart failure Stress (takotsubo) cardiomyopathy Severe pulmonary embolism or pulmonary hypertension Sepsis and critically ill patients Renal failure Severe acute neurologic diseases (e.g., stroke, subarachnoid hemorrhage) Infiltrative diseases (e.g., amyloidosis, sarcoidosis) Strenuous exercise

From Thygesen K, Alpert JS, White HD, et al: Universal definition of myocardial infarction. *J Am Coll Cardiol* 60:1581, 2012.

leading to expansion of the infarct. In some patients a vicious circle of dilation begetting further dilation ensues. The degree of ventricular dilation, which depends closely on infarct size, patency of the infarct-related artery, and activation of the renin-angiotensin-aldosterone system (RAAS), can be favorably modified by inhibitors of this system, even in the absence of symptomatic LV dysfunction.^{49,50}

With time, edema and ultimately fibrosis increase the stiffness of the infarcted myocardium back to and beyond control values. Increasing stiffness in the infarcted zone of myocardium improves LV function because it prevents paradoxical systolic wall motion (dyskinesia).

The likelihood of clinical symptoms developing correlates with specific parameters of LV function. The earliest abnormality is ventricular stiffness in diastole (see later), which is observed with infarcts involving only a small portion of the left ventricle on angiographic examination. When the abnormally contracting segment exceeds 15%, the ejection fraction may decline and LV end-diastolic pressure and volume increase. Risk for the development of physical signs and symptoms of LV failure also increases in proportion to increasing areas of abnormal LV wall motion. Clinical heart failure accompanies areas of abnormal contraction exceeding 25%, and cardiogenic shock, often fatal, is associated with loss of more than 40% of the LV myocardium.

Unless extension of the infarct occurs, some improvement in wall motion takes place during the healing phase, with recovery of function occurring in initially reversibly injured (stunned) myocardium (see Figs. 51-11 and 51-12). Regardless of the age of the infarct, patients who continue to demonstrate abnormal wall motion involving 20% to 25% of the left ventricle will probably manifest hemodynamic signs of LV failure, with its attendant poor prognosis for long-term survival.

Diastolic Function

The diastolic properties of the left ventricle (see Chapters 21, 22, and 27) change in infarcted and ischemic myocardium. These

alterations are associated with a decrease in the peak rate of decline in LV pressure (peak—dP/dt), an increase in the time constant of the fall in LV pressure, and an initial rise in LV end-diastolic pressure. Over a period of several weeks, end-diastolic volume increases and diastolic pressure begins to fall toward normal. As with impairment of systolic function, the magnitude of the diastolic abnormality appears to be related to the size of the infarct.

Circulatory Regulation

Patients with STEMI have an abnormality in circulatory regulation. The process begins with an anatomic or functional obstruction in the coronary vascular bed that results in regional myocardial ischemia and, if the ischemia persists, in infarction (Fig. 51-14). If the infarct is of sufficient size, it depresses overall LV function such that LV stroke volume falls and filling pressure rises.⁵¹ A marked depression in LV stroke volume ultimately lowers aortic pressure and reduces coronary perfusion pressure; this condition may intensify myocardial ischemia and thereby initiate a vicious circle (Fig. 51-14) leading to cardiogenic shock, which occurs in 5% to 8% of patients with STEMI.^{52,53} Systemic inflammation secondary to myocardial injury leads to the release of cytokines that contribute to the vasodilation and decreased systemic vascular resistance.⁵² The inability of the left ventricle to empty normally also increases preload; that is, it dilates the well-perfused, normally functioning portion of the left ventricle. This compensatory mechanism tends to restore stroke volume to normal levels, but at the expense of a reduced ejection fraction. Dilation of the left ventricle also elevates ventricular afterload, however, because Laplace's law dictates that at any given arterial pressure, the dilated ventricle must develop higher wall tension. This increased afterload not only depresses LV stroke volume but also elevates myocardial oxygen consumption, which in turn intensifies the myocardial ischemia. When regional myocardial dysfunction is limited and the function of the remainder of the left ventricle is normal, compensatory mechanisms—especially hyperkinesis of the nonaffected portion of the ventricle—sustain overall LV function. If a large portion of the left ventricle ceases to function, pump failure occurs.

Ventricular Remodeling (See also Chapter 22)

As a consequence of STEMI, the changes in LV size, shape, and thickness involving both the infarcted and noninfarcted segments of the ventricle described earlier occur and are collectively referred to as *ventricular remodeling*—which in turn can influence ventricular function and prognosis.⁵⁴ Changes in LV dilation combined with hypertrophy of residual noninfarcted myocardium cause remodeling. After infarct size, other important factors driving the process of LV dilation are ventricular volume, loading conditions, and infarct artery patency.^{48,55} Elevated ventricular pressure contributes to increased wall stress and the risk for infarct expansion, but a patent infarct artery accelerates myocardial scar formation and increases tissue turgor in the infarct zone, thereby reducing the risk for infarct expansion and ventricular dilation.

Infarct Expansion

An increase in the size of the infarcted segment, known as *infarct expansion*, is defined as “acute dilation and thinning of the area of infarction not explained by additional myocardial necrosis.” Infarct expansion appears to result from a combination of slippage between muscle bundles, which reduces the number of myocytes across the infarct wall; disruption of normal myocardial cells; and destruction of extracellular matrix within the necrotic zone.⁵⁶ Infarct expansion involves thinning and dilation of the infarct zone before the formation of a firm, fibrotic scar. The degree of infarct expansion appears to be related to preinfarction wall thickness, with existing hypertrophy possibly protecting against infarct thinning. On a cellular level, the degree of expansion and worsening remodeling depends on the intensity of the inflammatory response to the necrotic cells. Suppression of cytokine expression and stimulation may minimize the degree of inflammation and thus final infarct size.⁵⁶ The apex, the thinnest

EMOTIONAL AND PHYSICAL STRESS

FIGURE 51-13 A proposed mechanism for takotsubo, or stress-mediated, cardiomyopathy begins with sudden and severe emotional stress, which activates central autonomic network neurons expressing estrogen receptors. Simultaneously, sympathetic neuronal and adrenomedullary hormonal outflow increases dramatically and results in release of epinephrine (Epi) from the adrenal medulla combined with the release of norepinephrine (NE) from cardiac and extracardiac sympathetic nerves, which stimulate adrenoceptors in the blood vessels of the heart. Contraction of resistance vessels rapidly increases systemic blood pressure and cardiac afterload. High circulating levels of NE and Epi can precipitate catecholamine toxicity in cardiomyocytes via occupation of adrenoceptors. The typical hypercontraction of the basal sections of the heart, which leads to functional basal obstruction of LV outflow, further exacerbates LV wall stress and increases end-diastolic pressure. ANP = atrial natriuretic peptide; HSP70 = heat shock protein 70; NO = nitric oxide. (From Akashi YJ, Goldstein DS, Barbaro G, Ueyama T: Takotsubo cardiomyopathy: A new form of acute, reversible heart failure. *Circulation* 118:2754, 2008.)

region of the left ventricle, is particularly vulnerable to infarct expansion. Infarction of the apex secondary to occlusion of the left anterior descending coronary artery causes the radius of curvature at the apex to increase, thereby exposing this normally thin region to a marked elevation in wall stress.

Infarct expansion is associated with both higher mortality and a higher incidence of nonfatal complications, such as heart failure and ventricular aneurysm. Infarct expansion is best recognized as elongation of the noncontractile region of the ventricle on echocardiography or CMR. When the expansion is severe enough to cause symptoms, the most characteristic clinical findings are deterioration of systolic function, new or worsening pulmonary congestion, and the development of ventricular arrhythmias.

Ventricular Dilation

Although infarct expansion plays an important role in the ventricular remodeling that occurs early following MI, remodeling is also caused by dilation of the viable portion of the ventricle, which commences immediately after STEMI and progresses for months or years thereafter. A shift of the pressure-volume curve of the left ventricle to the right, which results in a larger LV volume at any given diastolic pressure, may accompany dilation. This dilation of the noninfarcted zone can be viewed as a compensatory mechanism that maintains stroke volume in the presence of a large infarction. STEMI places an

extra load on the residual functioning myocardium, a burden that presumably causes the compensatory hypertrophy of the noninfarcted myocardium. This hypertrophy could help compensate for the functional impairment caused by the infarct and may be responsible for some of the hemodynamic improvement seen in some patients in the months after infarction.

Effects of Treatment

Several factors can affect ventricular remodeling after STEMI, notably infarct size (see Figs. 51-11 and 51-12). Acute reperfusion and other measures to restrict the extent of myocardial necrosis limit the increase in ventricular volume after STEMI. Multiple pharmacologic agents aimed at limiting infarct size have undergone evaluation in clinical trials, although few have produced significant results in adequately powered phase III investigations (see Chapter 52). The second factor is scar formation in the infarct. Glucocorticosteroids and nonsteroidal anti-inflammatory agents given early after MI can cause scar thinning and greater infarct expansion, whereas RAAS inhibitors attenuate the ventricular enlargement.⁴⁹ Additional beneficial consequences of inhibition of angiotensin II that may contribute to myocardial protection include attenuation of endothelial dysfunction and direct antiatherogenic effects. Inhibition of aldosterone action may limit excessive fibrosis and decrease the development of ventricular arrhythmias.⁵⁷

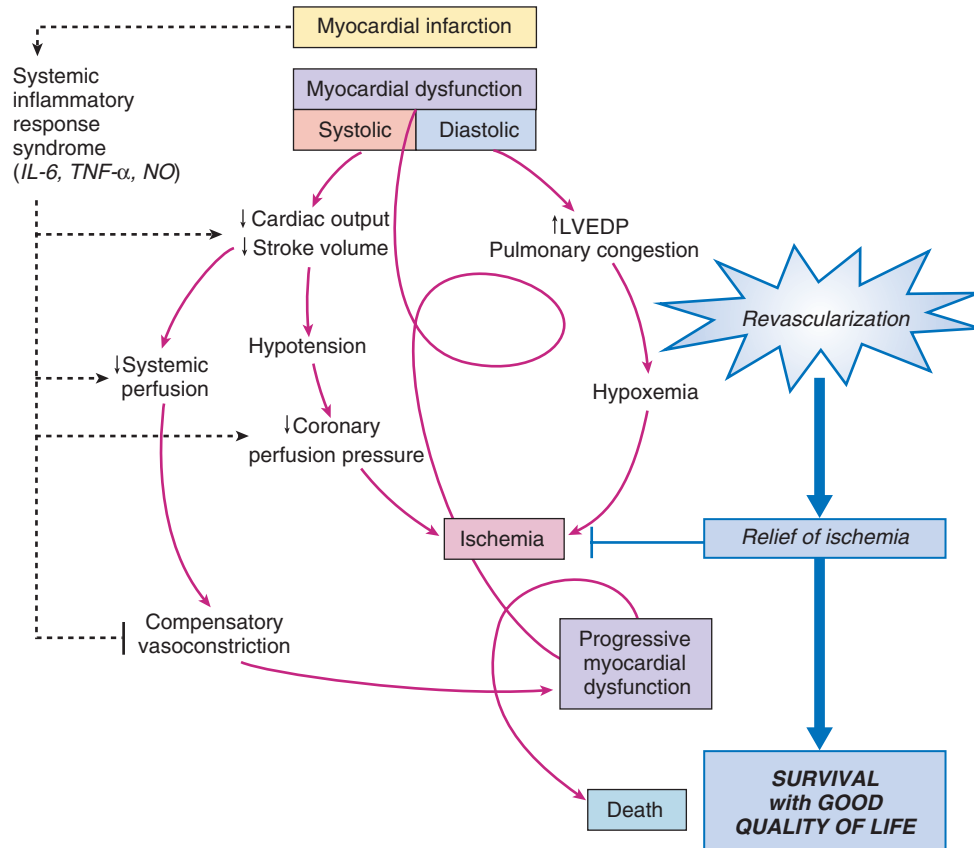

FIGURE 51-14 Current concept of the pathophysiology of cardiogenic shock. Myocardial injury causes systolic and diastolic dysfunction. A decrease in cardiac output leads to a decrease in systemic and coronary perfusion. The decreased perfusion exacerbates ischemia and causes cell death in the infarct border zone and the remote zone of myocardium. Inadequate systemic perfusion triggers reflex vasoconstriction, which is usually insufficient. Systemic inflammation may play a role in limiting the peripheral vascular compensatory response and may contribute to the myocardial dysfunction. Whether inflammation plays a causal role or is only an epiphenomenon remains unclear. Revascularization leads to relief of ischemia. Demonstration of an increase in cardiac output or the LV ejection fraction as the mechanism of benefit of revascularization has not been possible, but revascularization significantly increases the likelihood of survival with good quality of life. IL-6 = interleukin-6; LVEDP = LV end-diastolic pressure; NO = nitric oxide; TNF- α = tumor necrosis factor- α . (From Reynolds HR, Hochman JS: Cardiogenic shock: Current concepts and improving outcomes. *Circulation* 117:686, 2008.)

Pathophysiology of Other Organ Systems

Pulmonary Function

Arterial oxygen tension is inversely related to pulmonary artery diastolic pressure, which suggests that if patients with STEMI become hypoxic, the increased pulmonary capillary hydrostatic pressure can promote interstitial edema and consequently result in arteriolar and bronchiolar compression that ultimately causes perfusion of poorly ventilated alveoli with resultant hypoxemia (see Chapter 22). In addition to hypoxemia, diffusion capacity decreases. Hyperventilation often occurs in patients with STEMI and may cause hypocapnia and respiratory alkalosis, particularly in restless, anxious patients with pain. Pulmonary extravascular (interstitial) water content, LV filling pressure, and the clinical signs and symptoms of LV failure are correlated. The increase in pulmonary extravascular water may cause the alterations in pulmonary mechanics observed in patients with STEMI (i.e., reduction in airway conductance, pulmonary compliance, forced expiratory volume, and midexpiratory flow rate and an increase in closing volume, presumably related to the widespread closure of small, dependent airways during the first 3 days after STEMI). Ultimately, severe increases in extravascular water may lead to pulmonary edema. Virtually all lung volume indices—total lung capacity, functional residual capacity, and residual volume, as well as vital capacity—fall during STEMI.

Reduction of the Affinity of Hemoglobin for Oxygen

In patients with MI, particularly when complicated by LV failure or cardiogenic shock, the affinity of hemoglobin for oxygen falls (i.e., P50 increases). The increase in P50 results from increased levels of

erythrocyte 2,3-diphosphoglycerate, which is an important compensatory mechanism that is responsible for an estimated 18% increase in release of oxygen from oxyhemoglobin in patients with cardiogenic shock.

Endocrine Function

Pancreas. Although patients with STEMI often have absolute concentrations of blood insulin in the normal range, these levels are usually inappropriately low for their blood sugar concentration, and relative insulin resistance may be present as well. Patients with cardiogenic shock frequently have marked hyperglycemia with depressed levels of circulating insulin. Abnormalities in insulin secretion and the resultant impaired glucose tolerance appear to be due to a reduction in pancreatic blood flow as a consequence of the splanchnic vasoconstriction accompanying severe LV failure. In addition, increased activity of the sympathetic nervous system with augmented circulating catecholamines inhibits insulin secretion and increases glycogenolysis, which also contributes to elevated blood sugar.⁵⁸

Glucose permits the generation of ATP by anaerobic glycolysis, as opposed to free fatty acids, which require aerobic conditions to furnish ATP.⁵⁹ Because hypoxic heart muscle derives a considerable proportion of its energy from the metabolism of glucose (see Chapter 21) and because glucose uptake by the myocardium requires insulin, insulin deficiency can jeopardize the availability of energy. These metabolic considerations, combined with epidemiologic observations that patients with diabetes have a markedly worse prognosis, served as the foundation for efforts to administer insulin-glucose infusions to diabetic patients with STEMI. To date, however, none of these studies has demonstrated clear benefit (see Chapter 52).^{60,61}

Adrenal Medulla. Plasma and urinary catecholamine levels peak during the first 24 hours after the onset of chest pain, with the

greatest rise in plasma catecholamine secretion occurring during the first hour after the onset of STEMI. These high levels of circulating catecholamines in patients with STEMI correlate with the occurrence of serious arrhythmias and result in an increase in myocardial oxygen consumption, both directly and indirectly, as a consequence of catecholamine-induced elevation of circulating free fatty acids. The concentration of circulating catecholamines correlates with the extent of myocardial damage and the incidence of cardiogenic shock, as well as with both early and late mortality rates.

Circulating catecholamines enhance platelet aggregation; when this occurs in the coronary microcirculation, release of the potent local vasoconstrictor thromboxane A_2 may further impair cardiac perfusion. The marked increase in sympathetic activity associated with STEMI serves as the foundation for beta-adrenergic receptor blocker (beta-blocking agent) regimens in the acute phase.

Activation of the Renin-Angiotensin-Aldosterone System. Noninfarcted regions of the myocardium appear to exhibit activation of the tissue RAAS with increased production of angiotensin II. Both locally and systemically generated angiotensin II can stimulate the production of various growth factors, such as platelet-derived growth factor and TGF- β , that promote compensatory hypertrophy in the noninfarcted myocardium, as well as control the structure and tone of the infarct-related coronary and other myocardial vessels. Additional potential actions of angiotensin II that have a more negative impact on the infarction process include the release of endothelin, PAI-1, and aldosterone, which may cause vasoconstriction, impaired fibrinolysis, and increased sodium retention, respectively.

Natriuretic Peptides. The peptides atrial natriuretic factor (ANF) and N-terminal pro-ANF are released from the cardiac atria in response to an elevation in atrial pressure. B-type natriuretic peptide (BNP) and its precursor N-terminal pro-BNP are secreted by atrial and ventricular myocardium. Given the larger mass of ventricular than atrial myocardium, the total amount of mRNA for BNP is higher in the ventricles than in the atria. Natriuretic peptides are released early after STEMI, with a peak at approximately 16 hours. Evidence shows that the natriuretic peptides released from the left ventricle during STEMI originate both from the infarcted myocardium and from viable noninfarcted myocardium. The rise in BNP and N-terminal pro-BNP after STEMI correlates with infarct size and regional wall motion abnormalities. Measurement of natriuretic peptides can provide useful information both early and late in the course of STEMI.^{62,63}

Adrenal Cortex. Plasma and urinary 17-hydroxycorticosteroids and ketosteroids, as well as aldosterone, rise markedly in patients with STEMI. Their concentrations correlate directly with the peak level of serum CK, thus implying an association between the stress imposed by larger infarcts and greater secretion of adrenal steroids. The magnitude of the elevation in cortisol correlates with infarct size and mortality. Glucocorticosteroids also contribute to impaired glucose tolerance.

Thyroid Gland. Although patients with STEMI are generally euthyroid clinically, serum triiodothyronine (T_3) levels can decrease transiently, a fall that is most marked on approximately the third day after the infarct. A rise in reverse T_3 usually accompanies this fall in T_3 , with variable changes or no change in thyroxine (T_4) and thyroid-stimulating hormone levels. The alteration in peripheral T_4 metabolism appears to correlate with infarct size and may be mediated by the rise in endogenous levels of cortisol that accompanies STEMI.

Renal Function. Both prerenal azotemia and acute renal failure can complicate the marked reduction in cardiac output that occurs in cardiogenic shock. On the other hand, an increase in circulating atrial natriuretic peptide occurs following STEMI and correlates with the severity of LV failure. An increase in natriuretic peptide also occurs when RV infarction accompanies inferior wall infarction, thus suggesting that this hormone may contribute to the hypotension that accompanies RV infarction.

Hematologic Alterations

Platelets. STEMI generally occurs in the presence of extensive coronary and systemic atherosclerotic plaque, which may serve as the site for the formation of platelet aggregates—a sequence suggested as the initial step in the process of coronary thrombosis, coronary occlusion, and subsequent MI. Platelets from patients with STEMI have an increased propensity for aggregation both systemically and locally in the area of disrupted plaque, and they release vasoactive substances.⁶⁴

Hemostatic Markers. Elevated levels of serum fibrinogen degradation products, an end product of thrombosis, as well as release of distinctive proteins when platelets are activated (such as platelet factor 4 and beta-thromboglobulin), occur in some patients with STEMI. Fibrinopeptide A (FPA), a protein released from fibrin by thrombin, is a marker of ongoing thrombosis and increases during the early hours

of STEMI. Marked elevation of hemostatic markers such as FPA, TAT, and F1.2 is associated with an increased risk for mortality in patients with STEMI. Interpretation of coagulation test results in patients with STEMI may be complicated by elevated blood levels of catecholamines, concomitant shock, and/or pulmonary embolism—conditions that may alter various tests of platelet and coagulation function. Additional factors that affect coagulation test results in patients with STEMI include the type and dosage of antithrombotic agent and reperfusion of the infarct artery.

Leukocytes. Leukocytosis usually accompanies STEMI in proportion to the magnitude of the necrotic process, elevated glucocorticoid levels, and possibly inflammation in the coronary arteries. The magnitude of the elevation in leukocyte count is associated with in-hospital mortality after STEMI.⁶⁵ Experimental evidence suggests that the surge in catecholamines after coronary occlusion can mobilize leukocyte progenitors from bone marrow, thereby sustaining the inflammatory response following infarction.⁶⁶

Blood Viscosity. Clinical and epidemiologic studies suggest that several hemostatic and hemorheologic factors (e.g., fibrinogen, factor VII, plasma viscosity, hematocrit, red blood cell aggregation, total white blood cell count) participate in the pathophysiology of atherosclerosis and play an integral role in acute thrombotic events. An increase in blood viscosity also occurs in patients with STEMI and can be attributed to hemoconcentration during the first few days and later to elevated serum concentrations of alpha₂-globulin and fibrinogen, components of the acute-phase response to tissue necrosis that also cause the elevated sedimentation rate characteristic of STEMI.

CLINICAL FEATURES

Predisposing Factors

Up to half of patients with STEMI have an identifiable precipitating factor or prodromal symptoms. Unusually heavy exercise (particularly in fatigued or habitually inactive patients) and emotional stress can precipitate STEMI.⁶⁷ Such infarctions could result from marked increases in myocardial oxygen consumption in the presence of severe coronary arterial narrowing.

Accelerating angina and rest angina, two patterns of unstable angina, may culminate in STEMI (see Fig. 51-1). Noncardiac surgical procedures may also precede STEMI. Perioperative risk stratification and preventive measures may limit STEMI and cardiac-related mortality (see Chapter 80).⁶⁸ Reduced myocardial perfusion secondary to hypotension (e.g., hemorrhagic or septic shock) and the increased myocardial oxygen demands caused by aortic stenosis, fever, tachycardia, and agitation can also contribute to myocardial necrosis. Other factors reported to predispose to STEMI include respiratory infections, hypoxemia from any cause, pulmonary embolism, hypoglycemia, administration of ergot preparations, cocaine use, sympathomimetics, serum sickness, allergy, and rarely, wasp stings. In patients with Prinzmetal angina (see Chapter 54), STEMI may develop in the territory of the coronary artery that repeatedly undergoes spasm.

Circadian Periodicity

The time of onset of STEMI has a pronounced circadian periodicity, with the peak incidence of events occurring in the morning.²⁸ Circadian rhythms affect many physiologic and biochemical variables; the early morning hours are associated with increases in plasma catecholamines and cortisol and in platelet aggregability. Interestingly, the characteristic circadian peak is *absent* in patients receiving a beta-blocking agent or aspirin before the development of STEMI. The concept of “triggering” a STEMI is complex and probably involves the superimposition of multiple factors such as the time of day, season, and the stress of natural disasters.⁶⁹

History (See also Chapters 11, 50, and 53) Prodromal Symptoms

The patient's history remains crucial to establishing a diagnosis of STEMI. Chest discomfort resembling classic angina pectoris usually

characterizes the prodrome, but it occurs at rest or with less activity than usual. Yet the symptoms are often not disturbing enough to induce patients to seek immediate medical attention, and if they do, they may not be hospitalized. A feeling of general malaise or frank exhaustion frequently accompanies other symptoms preceding STEMI.

Nature of the Pain

Pain in patients with STEMI varies in intensity; in most patients it is severe and in some instances is intolerable. The pain is prolonged—it generally lasts for more than 30 minutes and frequently for several hours. The patient usually describes the discomfort as constricting, crushing, oppressing, or compressing and often complains of a sensation of a heavy weight or a squeezing in the chest. Although patients typically describe the discomfort as a choking, viselike, or heavy pain, it can also be characterized as a stabbing, knifelike, boring, or burning discomfort. The discomfort usually localizes retrosternally and frequently spreads to both sides of the anterior part of the chest, with a predilection for the left side. Often the pain radiates down the ulnar aspect of the left arm and produces a tingling sensation in the left wrist, hand, and fingers. Some patients note only a dull ache or numbness of the wrists in association with severe substernal or precordial discomfort. In some patients, pain from STEMI may begin in the epigastrium and simulate a variety of abdominal disorders, which often causes STEMI to be misdiagnosed as “indigestion.” In other patients the discomfort of STEMI radiates to the shoulders, upper extremities, neck, jaw, and interscapular region, again usually favoring the left side. In patients with preexisting angina pectoris, the pain of infarction generally resembles that of angina with respect to location, but it is normally much more severe, lasts longer, and is not relieved by rest and nitroglycerin.

STEMI pain may subside by the time that the physician first encounters the patient (or the patient reaches the hospital), or it may persist for many hours. Opiates, particularly morphine, usually relieve the pain (see Chapter 52). Both angina pectoris and STEMI pain are thought to arise from nerve endings in ischemic or injured, but not necrotic myocardium. Thus in cases of STEMI, stimulation of nerve fibers in an ischemic zone of myocardium surrounding the necrotic central area of infarction probably gives rise to the pain.

The pain often disappears suddenly and completely following restoration of blood flow to the infarct territory. In patients in whom reocclusion occurs after fibrinolysis, pain recurs if the initial reperfusion has left viable myocardium. Thus what has previously been thought of as the “pain of infarction,” sometimes lasting for many hours, probably represents pain caused by ongoing ischemia. The recognition that pain implies ischemia and not infarction heightens the importance of seeking ways to relieve the ischemia, for which the pain is a marker. This finding suggests that clinicians should *not* be complacent about ongoing cardiac pain in any circumstances. In some patients—particularly older adults, patients with diabetes, and heart transplantation recipients—STEMI is manifested clinically not by chest pain but rather by symptoms of acute LV failure and chest tightness or by marked weakness or frank syncope. Diaphoresis, nausea, and vomiting may accompany these symptoms.

Other Symptoms

Nausea and vomiting may occur, presumably because of activation of the vagal reflex or stimulation of LV receptors as part of the Bezold-Jarisch reflex. These symptoms occur more commonly in patients with inferior STEMI than in those with anterior STEMI. Moreover, nausea and vomiting are common side effects of opiates. When the pain of STEMI is epigastric in location and associated with nausea and vomiting, the clinical picture can easily be confused with that of acute cholecystitis, gastritis, or peptic ulcer. Occasionally, a patient complains of diarrhea or a violent urge to defecate during the acute phase of STEMI. Other symptoms include feelings of profound weakness, dizziness, palpitations, cold perspiration, and a sense of impending doom. On occasion, symptoms arising from an episode of cerebral embolism or other systemic arterial embolism can herald STEMI. Chest discomfort may not accompany these symptoms.

Differential Diagnosis

STEMI pain may simulate that of acute pericarditis (see Chapter 71), which is usually associated with some pleuritic features—it is aggravated by respiratory movements and coughing and often involves the shoulder, ridge of the trapezius, and neck. An important feature that distinguishes pericardial pain from ischemic discomfort is that ischemic discomfort does not radiate to the trapezius ridge, a characteristic site of radiation of pericardial pain. Pleural pain is generally sharp, knifelike, and aggravated in a cyclical fashion by each breath, which distinguishes it from the deep, dull, steady pain of STEMI. Pulmonary embolism (see Chapter 73) typically produces pain laterally in the chest, is often pleuritic in nature, and may be associated with hemoptysis. The pain caused by acute aortic dissection (see Chapter 57) is usually localized to the center of the chest, is extremely severe and described by the patient as a “ripping” or “tearing” sensation, is at its maximal intensity shortly after onset, persists for many hours, and frequently radiates to the back or lower extremities. Often, one or more major arterial pulses are absent. Pain arising from the costochondral and chondrosternal articulations may be associated with localized swelling and redness; it is generally sharp and “darting” and is characterized by marked localized tenderness. Episodes of retrosternal discomfort induced by peristalsis in patients with increased esophageal stiffness and episodes of sustained esophageal contraction can mimic the pain of STEMI.

Silent ST-Elevation Myocardial Infarction with Atypical Features

Nonfatal STEMI can go unrecognized by the patient and be manifested only on subsequent routine electrocardiographic or postmortem examinations. Of these unrecognized infarctions, approximately half are truly silent, with patients unable to recall any symptoms whatsoever. The other half of patients with so-called *silent infarction* can recall an event characterized by symptoms compatible with acute infarction when leading questions are posed after the electrocardiographic abnormalities are discovered. Unrecognized or silent infarction occurs more commonly in patients without antecedent angina pectoris and in patients with diabetes and hypertension and are typically detected by identification of new wall motion abnormalities, fixed perfusion defects, or pathologic Q waves.⁷⁰ Silent STEMI is often followed by silent ischemia (see Chapter 54). The prognosis of patients with silent and symptomatic manifestations of STEMI appears to be quite similar.^{71,72}

Atypical features of STEMI include the following: (1) heart failure (i.e., dyspnea without pain beginning *de novo* or worsening of established failure), (2) classic angina pectoris without a particularly severe or prolonged episode, (3) atypical location of the pain, (4) central nervous system manifestations resembling those of stroke secondary to a sharp reduction in cardiac output in a patient with cerebral arteriosclerosis, (5) apprehension and nervousness, (6) sudden mania or psychosis, (7) syncope, (8) overwhelming weakness, (9) acute indigestion, and (10) peripheral embolization. Women are seen more frequently than men with “atypical” features, and hence a high “index of suspicion” is required by the clinician (see Chapter 77).

Physical Examination (See also Chapter 11) General Appearance

Patients suffering from STEMI often appear anxious and in considerable distress. An anguished facial expression is common, and—in contrast to patients with severe angina pectoris, who often lie, sit, or stand still because all forms of activity increase the discomfort—some patients suffering from STEMI may be restless and move about in an effort to find a comfortable position. They often massage or clutch their chests and frequently describe their pain with a clenched fist held against the sternum (the Levine sign, named after Dr. Samuel A. Levine). In patients with LV failure and sympathetic stimulation, cold perspiration and skin pallor may be evident; they typically sit or are propped up in bed and gasp for breath. Between breaths they may complain of chest discomfort or a feeling of suffocation. Cough producing frothy, pink, or blood-streaked sputum may occur.

Patients in cardiogenic shock often lie listlessly and make few spontaneous movements. Their skin is cool and clammy, with a bluish or mottled color over the extremities, and there is marked facial pallor with severe cyanosis of the lips and nail beds. Depending on the degree of cerebral perfusion, a patient in shock may converse normally or be confused.

Heart Rate

The heart rate can vary from marked bradycardia to a rapid regular or irregular tachycardia, depending on the underlying rhythm and degree of LV failure. Most commonly the pulse is rapid and regular initially (sinus tachycardia at 100 to 110 beats/minute) and slows as the patient's pain and anxiety are relieved; premature ventricular beats are common.

Blood Pressure

Most patients with uncomplicated STEMI are normotensive, although the reduced stroke volume accompanying the tachycardia can cause declines in systolic and pulse pressure and elevation of diastolic pressure. In previously normotensive patients, a hypertensive response is occasionally seen during the first few hours, presumably as a consequence of adrenergic discharge secondary to pain, anxiety, and agitation. Previously hypertensive patients often become normotensive without treatment after STEMI, although many of them eventually regain their elevated levels of blood pressure, generally 3 to 6 months after infarction. In patients with massive infarction, arterial pressure falls acutely because of LV dysfunction and may be exacerbated by morphine and/or nitrates, which cause venous pooling; as recovery occurs, arterial pressure tends to return to preinfarction levels.

Patients in cardiogenic shock by definition have systolic pressure below 90 mm Hg and evidence of end-organ hypoperfusion. Hypotension alone does not necessarily signify cardiogenic shock, however; some patients with inferior infarction and activation of the Bezold-Jarisch reflex may also transiently have systolic blood pressure below 90 mm Hg. Their hypotension eventually resolves spontaneously, although the process can be accelerated by intravenous atropine (0.5 to 1 mg) and assumption of the Trendelenburg position. Other patients who are initially only slightly hypotensive may demonstrate gradually falling blood pressure with a progressive reduction in cardiac output over a period of several hours or days as cardiogenic shock develops because of increasing ischemia and extension of infarction (Fig. 51-14). Evidence of autonomic hyperactivity is common and varies in type with the location of the infarction. More than half of patients with inferior STEMI have evidence of excess parasympathetic stimulation, with hypotension, bradycardia, or both evident during initial evaluation, whereas approximately half of patients with anterior STEMI show signs of sympathetic excess and have hypertension, tachycardia, or both.

Temperature and Respiration

Fever, a nonspecific response to tissue necrosis, develops in most patients with extensive STEMI within 24 to 48 hours of the onset of infarction. Body temperature often begins to rise within 4 to 8 hours after the onset of infarction, and rectal temperature may reach 38.3°C to 38.9°C (101°F to 102°F). The fever usually resolves by the fourth or fifth day after infarction.

The respiratory rate may rise slightly soon after the development of STEMI; in patients without heart failure, it results from anxiety and pain and returns to normal with treatment of the physical and psychological discomfort. In patients with LV failure, the respiratory rate correlates with the severity of the failure; patients with pulmonary edema may have respiratory rates exceeding 40 per minute. However, the respiratory rate is not necessarily elevated in patients with cardiogenic shock. Cheyne-Stokes (periodic) respiration may occur in elderly individuals with cardiogenic shock or heart failure, particularly after opiate therapy or in the presence of cerebrovascular disease.

Jugular Venous Pulse

The jugular venous pulse is usually normal. The *a* wave may be prominent in patients with pulmonary hypertension secondary to LV

failure or reduced compliance. In contrast, RV infarction (regardless of whether it accompanies LV infarction) often results in marked jugular venous distention and, when complicated by necrosis or ischemia of RV papillary muscles, in the tall *c-v* waves of tricuspid regurgitation. Patients with STEMI and cardiogenic shock generally have elevated jugular venous pressure. In patients with STEMI, hypotension, and hypoperfusion (findings that may resemble those of patients with cardiogenic shock) who have flat neck veins, the depression in LV performance is probably related, at least in part, to hypovolemia. Differentiation can be made only by assessing LV performance with echocardiography or by measuring LV filling pressure with a pulmonary artery flotation catheter.

Carotid Pulse

Palpation of the carotid arterial pulse provides a clue to LV stroke volume: a small pulse suggests reduced stroke volume, whereas a sharp, brief upstroke often occurs in patients with mitral regurgitation or a ruptured ventricular septum with a left-to-right shunt. Pulsus alternans reflects severe LV dysfunction.

The Chest

Moist rales are audible in patients in whom LV failure and/or a reduction in LV compliance with STEMI develops. Diffuse wheezing can occur in patients with severe LV failure. Cough with hemoptysis, suggesting pulmonary embolism with infarction, can also occur. In 1967, Thomas Killip proposed a prognostic classification scheme on the basis of the presence and severity of rales in patients with STEMI. Class I patients are free of rales and a third heart sound. Class II patients have rales, but only to a mild to moderate degree (<50% of lung fields), and may or may not have an *S*₃. Patients in class III have rales in more than half of each lung field and frequently have pulmonary edema. Finally, class IV patients are in cardiogenic shock. Despite the overall improvement in the mortality rate that has now been achieved in each class, when compared with data observed during original development of the classification scheme, it still remains useful today, as evidenced by data from large MI trials of patients with STEMI.^{73,74}

Cardiac Examination

Palpation

Palpation of the precordium may yield normal results, but in patients with transmural STEMI, it more commonly reveals a presystolic pulsation synchronous with an audible fourth heart sound, a finding reflecting vigorous left atrial contraction filling a ventricle with reduced compliance. In patients with LV systolic dysfunction, an outward movement of the left ventricle can be palpated in early diastole, coincident with a third heart sound.

Auscultation

HEART SOUNDS. The heart sounds, particularly the first sound, are frequently muffled and occasionally inaudible immediately after an infarct, and their intensity increases during convalescence. A soft first heart sound may also reflect prolongation of the PR interval. Patients with marked ventricular dysfunction and/or left bundle branch block may have paradoxical splitting of the second heart sound.

A fourth heart sound is almost universally present in patients in sinus rhythm with STEMI, but it has limited diagnostic value because it is commonly audible in most patients with chronic ischemic heart disease and is recordable, although not often audible, in many normal subjects older than 45 years.

A third heart sound in patients with STEMI usually reflects severe LV dysfunction with elevated ventricular filling pressure. It is caused by rapid deceleration of transmittal blood flow during protodiastolic filling of the left ventricle and is typically heard in patients with large infarctions. This sound is detected best at the apex with the patient in the left lateral recumbent position. A third heart sound may be caused not only by LV failure but also by increased inflow into the left ventricle, as occurs when mitral regurgitation or a ventricular septal defect complicates STEMI. Third and fourth heart sounds

emanating from the left ventricle are heard best at the apex; in patients with RV infarcts, these sounds can be heard along the left sternal border and increase on inspiration.

MURMURS. Systolic murmurs—transient or persistent—are commonly audible in patients with STEMI and generally result from mitral regurgitation secondary to dysfunction of the mitral valve apparatus (papillary muscle dysfunction, LV dilation). A new, prominent, apical holosystolic murmur accompanied by a thrill may represent rupture of a head of a papillary muscle (see Chapter 52). The findings in cases of rupture of the interventricular septum are similar, although the murmur and thrill are usually most prominent along the left sternal border and may be audible at the right sternal border as well. The systolic murmur of tricuspid regurgitation (caused by RV failure because of pulmonary hypertension and/or RV infarction or by infarction of an RV papillary muscle) is also heard along the left sternal border. It is characteristically intensified by inspiration and is accompanied by a prominent *c-v* wave in the jugular venous pulse and an RV fourth sound.

FRICTION RUBS. Pericardial friction rubs may be heard in patients with STEMI, especially in those sustaining large transmural infarctions.⁷⁵ Rubs are notorious for their evanescence and hence are probably even more common than reported. Although friction rubs can be heard within 24 hours or as late as 2 weeks after the onset of infarction, they occur most commonly on the second or third day. Occasionally, in patients with extensive infarction, a loud rub can be heard for many days. Patients with STEMI and a pericardial friction rub may have a pericardial effusion on echocardiographic study, but it only rarely causes the classic electrocardiographic changes of pericarditis. Delayed onset of the rub and the associated discomfort of pericarditis (as late as 3 months after infarction) is characteristic of the now rare post-MI (Dressler) syndrome.

Pericardial rubs are most readily audible along the left sternal border or just inside the apical impulse. Loud rubs may be audible over the entire precordium and even over the back. Occasionally, only the systolic portion of a rub is heard, which requires distinction from a systolic murmur, such as might result from rupture of the ventricular septum or mitral regurgitation.

Other Findings

Fundi

Hypertension, diabetes, and generalized atherosclerosis commonly accompany STEMI and can produce characteristic changes in the fundus. A funduscopic examination may provide information concerning the underlying vascular status, which can be particularly useful in patients unable to provide a detailed history.

Abdomen

Patients often interpret pain in the abdomen associated with nausea, vomiting, restlessness, and even abdominal distention as a sign of “indigestion,” and it results in self-medication with antacids; it can also suggest an acute abdominal process to the physician. Right-sided heart failure, characterized by hepatomegaly and a positive abdominojugular reflux, is unusual in patients with acute LV infarction but occurs in patients with severe and prolonged LV failure or RV infarction.

Extremities

Coronary atherosclerosis is often associated with systemic atherosclerosis, and therefore patients with STEMI may have a history of intermittent claudication and demonstrate the physical findings of peripheral vascular disease (see Chapter 58). Thus diminished peripheral arterial pulses, loss of hair, and atrophic skin in the lower extremities may be noted in patients with coronary artery disease. Peripheral edema is a manifestation of RV failure and, like congestive hepatomegaly, is unusual in patients with acute LV infarction. Cyanosis of the nail beds is common in patients with severe LV failure and is particularly striking in patients in cardiogenic shock.

Neuropsychiatric Findings

Except for the altered mental status that occurs in patients with STEMI who have markedly reduced cardiac output and cerebral

hypoperfusion, findings on neurologic examination are normal unless the patient has suffered cerebral embolism secondary to a mural thrombus. The coincidence between these two conditions can be explained by systemic hypotension caused by STEMI precipitating a cerebral infarction and the converse, as well as by mural emboli from the left ventricle causing cerebral emboli.

Patients with STEMI frequently exhibit alterations in their emotional state, including intense anxiety, denial, and depression. Medical staff caring for patients with STEMI must be sensitive to changes in the patient's emotional state; a calm, professional atmosphere, with thorough explanations of equipment and prognosis, can help alleviate the distress associated with STEMI.

Laboratory Findings

Serum Markers of Cardiac Damage

Myocardial injury can be detected by the presence of circulating proteins released from damaged myocardial cells. Even though the availability of serum and plasma cardiac markers with markedly enhanced sensitivity for myocardial injury has enabled clinicians to identify much lower levels of injury, it is important to clarify that biochemical tests of myocardial injury do not provide any direct insight into the cause of the damage.^{76,77} MI is the diagnosis given to myocardial injury that results from ischemia (Fig. 51-15).¹ Other nonischemic insults, such as myocarditis or direct myocardial toxins, may result in myocardial injury but should not be labeled MI. Moreover, the enhanced ability to detect myocardial damage has increased the number of cases of myocardial injury that result from non-plaque-related clinical events, thus necessitating the establishment of new criteria for MI (see Table 51-1, 51-2, and 51-4) that place the injury in clinical context.¹

Although the following section applies more to diagnostic decision making for patients with suspected ACS without ST-segment elevation (see Chapter 53), this chapter contains a general discussion of cardiac biomarkers because of the overlapping pathophysiologic concepts and methodology when biomarkers are used to evaluate patients with STEMI. It should be emphasized that clinicians should *not* wait for the results of biomarker assays to initiate treatment of patients with STEMI. Given the time urgency for reperfusion in patients with STEMI, the 12-lead ECG should serve to initiate such strategies.

Necrosis compromises the integrity of the sarcolemmal membrane; intracellular macromolecules (serum and plasma cardiac markers) begin to diffuse into the cardiac interstitium and ultimately into the microvasculature and lymphatics in the region of the infarct (Fig. 51-16; also see Table 51-4). The rate of appearance of these macromolecules in the peripheral circulation depends on several factors, including intracellular location, molecular weight, local blood and lymphatic flow, and the rate of elimination from blood.⁷⁸

Cardiac-Specific Troponins

The preferred biomarker to detect myocardial injury is cardiac troponin, which consists of three subunits that regulate the calcium-mediated contractile process of striated muscle.¹ These subunits include troponin C, which binds Ca^{2+} ; troponin I (TnI), which binds to actin and inhibits actin-myosin interactions; and troponin T (TnT), which binds to tropomyosin, thereby attaching the troponin complex to the thin filament (Fig. 51-16). Although most TnT is incorporated in the troponin complex, approximately 6% to 8% is dissolved in the cytosol; in contrast, approximately 2% to 3% of TnI is found in a cytosolic pool. Following myocyte injury, the initial release of cardiac-specific TnT and TnI is from the cytosolic pool, followed subsequently by release from the structural (myofilament-bound) pool (Fig. 51-16).⁷⁸ Different genes encode TnT and TnI in cardiac and skeletal muscle, thus permitting the production of specific antibodies for the cardiac forms (cTnT and cTnI), which enables quantitative measurement of them (Fig. 51-16).^{78,79} Detection of a rise and fall in cTnT or cTnI in the appropriate clinical setting is now at the center of the new diagnostic criteria for MI.¹

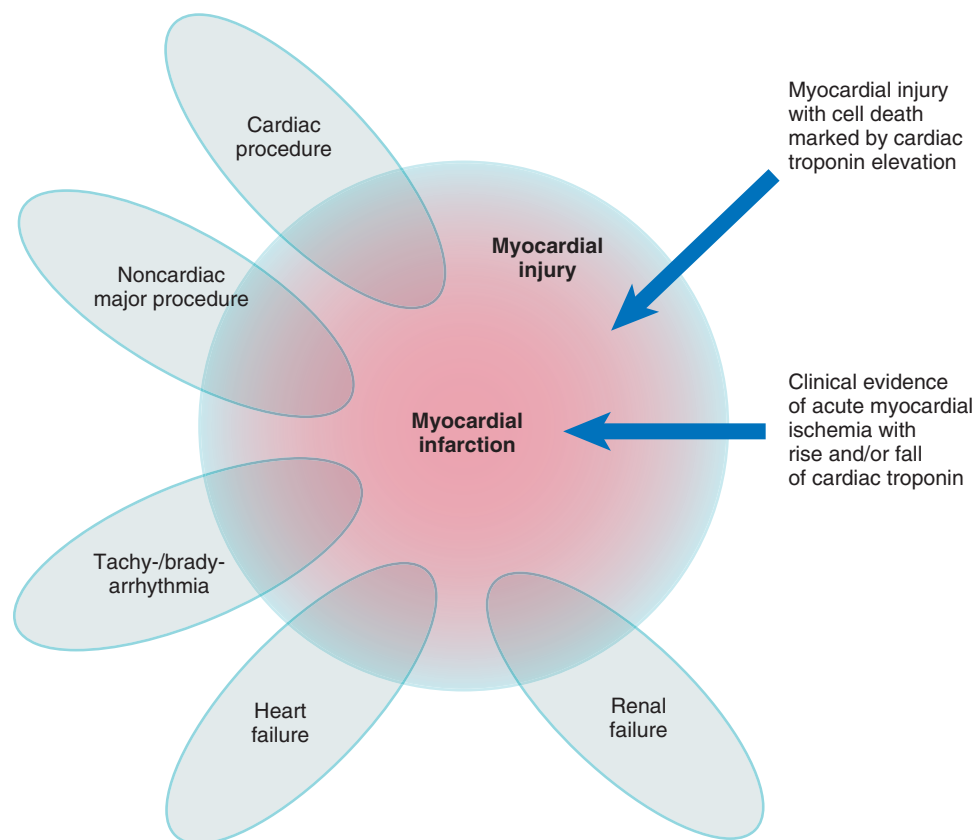

FIGURE 51-15 Myocardial ischemia and subsequent myocardial injury can result from a variety of clinical entities, including renal failure, heart failure, tachyarrhythmia or bradyarrhythmia, and cardiac or noncardiac procedures. Each of these scenarios can result in myocardial injury with cell death marked by the release of detectable circulating levels of cardiac troponin. However, each of these entities can also be associated with MI when there is clinical evidence of acute myocardial ischemia with a typical rise and/or fall in cardiac troponin levels. (From Thygesen K, Alpert JS, Jaffe AS, et al: Third universal definition of myocardial infarction. *J Am Coll Cardiol* 60:1581, 2012.)

When interpreting the results of assays for cTnT or cTnI, clinicians must recognize several analytic issues.^{77,80} cTnI assays are produced by multiple manufacturers using different troponin epitopes for detection, which has resulted in varying reference levels.^{78,79} A single manufacturer has commercialized cTnT, thereby leading to greater uniformity of the recommended cutoff. The release pattern of troponin complexes, conformational changes, and degradation into various troponin fragments may differentially affect the results of various commercial assays. Such post-translational modifications may provide insight into the underlying cause and timing of release (e.g., differentiating ischemia from myocarditis), but such applications remain investigational.

CUTOFF VALUES. Variations in the cutoff concentration for abnormal levels of cTnI in the clinically available immunoassays result in part from the different specificities of the antibodies used for detecting free and complexed cTnI. Thus clinicians should apply evidence-based cutoff values for the particular assay used in their laboratory.^{78,79} For both cTnT and cTnI, the definition of an abnormally increased level is a value exceeding that of 99% of a reference control group. Assays that have a level of imprecision (i.e., coefficient of variation) of less than 10% at the specific 99th percentile cutoff are optimal for clinical practice.¹

In patients with MI, cTnT and cTnI first begin to rise by approximately 3 hours after the onset of chest pain. Because of continuous release from a degenerating contractile apparatus in necrotic myocytes, elevations in cTnI may persist for 7 to 10 days after MI; elevations in cTnT may persist for up to 10 to 14 days. The prolonged time course of the elevation in cTnT and cTnI is advantageous for the late diagnosis of MI (Fig. 51-16). Patients with STEMI who undergo successful recanalization of the infarct-related artery have a rapid release of cardiac troponins, which can indicate reperfusion (Fig. 51-17).

HIGH-SENSITIVITY CARDIAC TROPONIN. Newer high-sensitivity assays that deliver enhanced analytic performance enable more precise measurement of very low concentrations of cardiac-specific troponin. Experts recommend that the term high-sensitivity troponin (hsTn) be reserved for assays that can detect cardiac troponin in more than 50% of an apparently healthy population.^{78,79} Such assays are substantially more sensitive than previous-generation assays but also have diminished clinical specificity for MI because they detect true myocardial injury in a variety of other clinical settings.⁷⁶ Nevertheless, in multiple studies of patients with nontraumatic chest pain, hsTn assays have improved overall diagnostic accuracy and enabled earlier detection of myocardial injury^{81,82} (see Fig. 51-16). Moreover, even low-level elevations in cardiac troponin detected with sensitive assays are associated with a worse prognosis.⁸³

Creatine Kinase-MB

If a cardiac-specific troponin assay is not available, CK-MB measured with a mass assay is the best alternative. Cardiac muscle contains both the MM and MB isoenzymes of CK. Other tissues can contain small quantities of the MB isoenzyme of CK, including the small intestine, tongue, diaphragm, uterus, and prostate. Strenuous exercise, particularly in trained long-distance runners or professional athletes, can cause an elevation in both total CK and CK-MB.

Because CK-MB can be detected in the blood of healthy subjects, the cutoff value for abnormal elevation of CK-MB is usually set a few units above the upper reference limit for a given laboratory (see Fig. 51-16). Like cardiac-specific troponin, the diagnosis of MI requires a maximal concentration of CK-MB exceeding the 99th percentile of values for sex-specific reference levels on two successive samples in a rise and fall pattern.¹ CK-MB is inaccurate in circumstances involving skeletal muscle injury.

Recommendations for Measurement of Serum Markers

All patients with suspected MI should undergo measurement of cardiac-specific troponin as soon as possible after the initial encounter. In patients with STEMI, the results of biomarker assessment should not delay interventions to achieve immediate reperfusion. From a cost-effectiveness perspective, measuring both a cardiac-specific troponin and CK-MB is unnecessary.¹ Routine diagnosis of MI can be accomplished by obtaining measurements at initial evaluation and then 3 to 6 hours later (see Table 50-1).¹ Later testing is required only when uncertainty exists regarding the onset of pain or when stuttering symptoms occur.

The universal definition of MI recommends classifying infarctions into five types (see Table 51-2), along with the magnitude of the infarction expressed as the fold elevation in cardiac biomarkers above the 99th percentile of the upper reference limit. An example from a clinical trial comparing prasugrel with clopidogrel as supportive antiplatelet therapy for moderate- to high-risk ACS patients undergoing PCI is shown in Figure 51-18.⁸⁴

Other Biomarkers. Other biomarkers may be used to noninvasively assess the potential causes and complications of MI. C-reactive protein (CRP) rises substantially in the setting of STEMI as a result of

the inflammatory response to myocyte necrosis and is associated with the subsequent risk for death or heart failure. BNP and related peptides reflect the hemodynamic impact of the MI and are associated with prognosis. Although both BNP and CRP enhance risk assessment, no clear guidance is available on how to structure specific therapeutic maneuvers in the setting of STEMI in response to these biomarkers.⁸⁵

FIGURE 51-16 Release of biomarkers into the circulation begins with prolonged ischemia and subsequent necrosis that results in loss of integrity of the cellular membranes. After disruption of the sarcolemmal membrane of the cardiomyocyte, the cytoplasmic pool of biomarkers is released first (left-most arrow in the bottom portion of the figure). Markers such as myoglobin and CK isoforms are released rapidly, and blood levels rise quickly above the cutoff limit. More protracted release of biomarkers from the disintegrating myofilaments follows and may continue for several days (three-headed arrow). Cardiac troponin levels rise to about 20 to 50 times the upper reference limit (the 99th percentile of values in a reference control group) in patients who have “classic” acute MI and sustain sufficient myocardial necrosis that results in abnormally elevated levels of CK-MB. Clinicians can now diagnose episodes of microinfarction by more sensitive assays that detect even small elevations in cardiac troponin above the upper reference limit, even though levels of CK-MB and troponin determined from older generations of assays may still be below the MI decision limit. Other causes of myocardial injury, such as renal failure or pulmonary embolism, can lead to detectable levels of cardiac troponin even without any coronary artery disease (lower panel). AMI = acute MI; CAD = coronary artery disease; UA = unstable angina. (Modified from Antman EM: Decision making with cardiac troponin tests. *N Engl J Med* 346:2079, 2002; Jaffe AS, Babuin L, Apple FS: Biomarkers in acute cardiac disease: The present and the future. *J Am Coll Cardiol* 48:1, 2006; and Reichlin T, Schindler C, Drexler B, et al: One-hour rule-out and rule-in of acute myocardial infarction using high-sensitivity cardiac troponin T. *Arch Intern Med* 172:1211, 2012.)

Future studies evaluating novel biomarkers should focus on unmet clinical scenarios such as earlier detection of MI, differentiation of type I from type II MI, and improved risk stratification.⁸⁶ Markers such as copeptin, pregnancy-associated plasma protein-A (PAPP-A), fms-like tyrosine kinase (Flt-1), heart-type fatty acid-binding protein (H-FABP), and growth differential factor-15 (GDF-15) may offer insight into the different pathophysiologic processes in MI.^{63,87}

Other Laboratory Measurements

Serum Lipids (See Chapter 45). During the first 24 to 48 hours after admission, total cholesterol and high-density lipoprotein (HDL) cholesterol remain at or near baseline values, but they generally fall after that. The fall in HDL cholesterol after STEMI is greater than the fall in total cholesterol; thus the ratio of total cholesterol to HDL cholesterol is no longer useful for risk assessment unless measured early after MI. A lipid profile should be obtained on all patients with STEMI who are admitted within 24 hours of symptoms.⁸⁸ Lipid levels may still be clinically useful for patients admitted beyond 24 to 48 hours,⁸⁹ although more accurate determinations of serum lipid levels are obtained about 8 weeks after the infarction has occurred.

Hematologic Findings. Elevation of the white blood cell count usually develops within 2 hours after the onset of chest pain, reaches a peak 2 to 4 days after infarction, and returns to normal in 1 week; the peak white blood cell count generally ranges between 12 and 15 × 10³/mL but occasionally rises to as high as 20 × 10³/mL in patients with large STEMI. Frequently there is an increase in the percentage of polymorphonuclear leukocytes and a shift of the differential count to band forms. An epidemiologic association has been reported, with a worse angiographic appearance of the culprit lesions and increased risk for adverse clinical outcomes the higher the white blood cell count at initial evaluation in patients with an ACS.⁹⁰

The erythrocyte sedimentation rate (ESR) is usually normal during the first day or two after infarction, even though fever and leukocytosis may be present. It then rises to a peak on the fourth or fifth day and may remain elevated for several weeks. The increase in the ESR does not correlate well with the size of the infarction or with prognosis. The hematocrit often increases during the first few days after infarction as a consequence of hemoconcentration.

The hemoglobin value at initial evaluation of a patient with STEMI powerfully and independently predicts major cardiovascular events. Of note is a J-shaped relationship between baseline hemoglobin values and clinical events. Cardiovascular mortality increases progressively as the initial hemoglobin value falls below 14 to 15 g/dL; conversely, it also rises as the hemoglobin level increases above 17 g/dL. The increased risk from anemia is probably related to diminished tissue delivery of oxygen, whereas the increased risk with polycythemia may be related to an increase in blood viscosity.⁹¹

Electrocardiography (See Chapter 12)

Serial changes on the ECG develop in most patients with STEMI, but many factors limit the usefulness of the ECG in diagnosing and localizing MI: the extent of myocardial injury, the age of the infarct, its

CARDIAC MARKERS IN STEMI

FIGURE 51-17 The kinetics of the release of CK-MB and cardiac troponin in patients who do not undergo reperfusion is shown in the solid blue and red curves as multiples of the URL. When patients with STEMI undergo reperfusion, as depicted in the dashed blue and red curves, the cardiac biomarkers are detected sooner and rise to a higher peak value but decline more rapidly, which results in a smaller area under the curve and limitation of infarct size. AMI = acute MI. (Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation* 110:e82, 2004.)

location, the presence of conduction defects, the presence of previous infarcts or acute pericarditis, changes in electrolyte concentrations, and the administration of cardioactive drugs. Abnormalities in the ST segment and T wave are quite nonspecific and may occur in a variety of conditions, including stable and unstable angina pectoris, ventricular hypertrophy, acute and chronic pericarditis, myocarditis, early repolarization, electrolyte imbalance, shock, and metabolic disorders, as well as following the administration of digitalis. Serial ECGs help in differentiating these conditions from STEMI. Transient changes favor angina or electrolyte disturbances, whereas persistent changes argue for infarction if other causes such as shock, administration of digitalis, and persistent metabolic disorders can be eliminated. Nevertheless, serial standard 12-lead ECGs remain an extremely useful method for the detection and localization of MI.⁹²

Analysis of the constellation of ECG leads showing ST elevation may also be useful for identifying the site of occlusion in the infarct artery (see Fig. 51-5).³¹ The extent of ST deviation on the ECG, location of the infarction, and the QRS duration correlate with the risk for adverse outcomes. Even when left bundle branch block is present on the ECG, MI can be diagnosed when striking ST-segment deviation is present beyond what can be explained by the conduction defect (Table 51-5). In addition to the diagnostic and prognostic information contained within the 12-lead ECG, the degree of ST-segment resolution provides valuable noninvasive information about the success of reperfusion for STEMI, regardless of whether it was achieved with fibrinolysis or primary coronary intervention (see Chapter 52).^{93,94}

Although general agreement exists on electrocardiographic and vector cardiographic criteria for the recognition of infarction of the anterior and inferior myocardial walls, less agreement exists on criteria for lateral and posterior infarcts. A consensus group has recommended elimination of the term “posterior” and suggests using “lateral” to be consistent with current understanding of the segmental anatomy of the heart as it sits in the thorax.³¹ The most recent universal definition of MI, however, retains the category of posterior MI.¹ Patients with an abnormal R wave in V₁ (0.04 second in duration and/or R/S ratio ≥ 1 in the absence of preexcitation or RV hypertrophy)

FIGURE 51-18 Top panel, Risk for cardiovascular death associated with new or recurrent type I MI stratified according to MI size. Bottom panel, Rates of the effect of prasugrel versus clopidogrel with respect to the total number of new or recurrent MIs; the incidence of MI (%) is classified by using the biomarker categories recommended by the universal definition of MI (see Table 51-2). The biomarker categories are groupings of fold elevations above the upper reference limit (URL) of normal. The data shown for each bar are derived from Kaplan-Meier estimates for the incidence of MI; the percent reductions represent the relative reductions in the hazard ratio for the development of an MI in the prasugrel versus clopidogrel groups. HRR = hazard ratio reduction. (From Morrow DA, Wiviott SD, White HD, et al: Effect of the novel thienopyridine prasugrel compared with clopidogrel on spontaneous and procedural myocardial infarction in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction 38. An application of the classification system from the universal definition of myocardial infarction. *Circulation* 119:2758, 2009; and Bonaca MP, Wiviott SD, Braunwald E, et al: American College of Cardiology/American Heart Association/European Society of Cardiology/World Heart Federation universal definition of myocardial infarction classification system and the risk of cardiovascular death: Observations from the TRITON-TIMI 38 trial [Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel-Thrombolysis in Myocardial Infarction 38]. *Circulation* 125:577, 2012.)

and inferior or lateral Q waves have an increased incidence of isolated occlusion of a dominant left circumflex coronary artery without collateral circulation; such patients have a lower ejection fraction, increased end-systolic volume, and higher complication rate than do those with inferior infarction because of isolated occlusion of the right coronary artery.

Although most patients bear the changes from an MI on the ECG for the rest of their lives, particularly if Q waves evolve, in a substantial minority the typical changes disappear, the Q waves regress, and findings on the ECG can even return to normal after a number of years. Under many circumstances, Q wave patterns simulate MI. Conditions that may mimic the electrocardiographic features of MI by producing a pattern of “pseudoinfarction” include ventricular hypertrophy, conduction disturbances, preexcitation, primary myocardial disease, pneumothorax, pulmonary embolism, amyloid heart disease, primary and metastatic tumors of the heart, traumatic heart disease, intracranial hemorrhage, hyperkalemia, pericarditis, early repolarization, and cardiac sarcoidosis.

TABLE 51-5 Electrocardiographic Manifestations of Myocardial Infarction

ELECTROCARDIOGRAPHIC MANIFESTATIONS OF ACUTE MYOCARDIAL ISCHEMIA (IN THE ABSENCE OF LEFT BUNDLE BRANCH BLOCK)	
ST Elevation	
New ST elevation at the J point in two contiguous leads with the following cut points:	
<ul style="list-style-type: none"> • ≥ 0.1 mV in all leads (except V_2-V_3) • In leads V_2-V_3 the following cut points apply: <ul style="list-style-type: none"> • ≥ 0.2 mV in men ≥ 40 years • ≥ 0.25 mV in men <40 years • ≥ 0.15 mV in women 	
ST Depression and T Wave Changes	
<ul style="list-style-type: none"> • New horizontal or downsloping ST depression ≥ 0.05 mV in two contiguous leads • T-wave inversion ≥ 0.1 mV in two contiguous leads with a prominent R wave or R/S ratio >1 	
ELECTROCARDIOGRAPHIC MANIFESTATIONS OF ISCHEMIA IN THE SETTING OF LEFT BUNDLE BRANCH BLOCK	
Electrocardiographic Criterion	Points
ST-segment elevation ≥ 1 mm and concordant with the QRS complex	5
ST-segment depression ≥ 1 mm in lead V_1 , V_2 , or V_3	3
ST-segment elevation ≥ 5 mm and discordant with the QRS complex	2
A score of ≥ 3 had a specificity of 98% for acute MI	
ELECTROCARDIOGRAPHIC CHANGES ASSOCIATED WITH PREVIOUS MYOCARDIAL INFARCTION (IN THE ABSENCE OF LEFT VENTRICULAR HYPERTROPHY AND LEFT BUNDLE BLOCK)	
Any Q wave in leads V_2 - V_3 ≥ 0.02 sec or a QS complex in leads V_2 and V_3	
Q wave ≥ 0.03 sec and ≥ 0.1 -mV deep or QS complex in leads I, II, aVL, aVF, or V_4 - V_6 in any 2 leads of a contiguous lead grouping (I, aVL; V_1 - V_6 ; II, III, aVF)	
R wave ≥ 0.04 sec in V_1 - V_2 and R/S ≥ 1 with a concordant positive T wave in absence of a conduction defect	

Based on criteria from O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e78, 2013.

Q-Wave and Non-Q-Wave Infarction

The presence or absence of Q waves on the surface ECG does not reliably distinguish between transmural and nontransmural (subendocardial) MI. Q waves on the ECG signify abnormal electrical activity but are not synonymous with irreversible myocardial damage. Also, the absence of Q waves may simply reflect the insensitivity of the standard 12-lead ECG, especially in zones of the left ventricle supplied by the left circumflex artery (see Fig. 51-5).³¹

Ischemia at a Distance

Patients with new Q waves and ST-segment elevation diagnostic of STEMI in one territory often have ST-segment depression in other territories. These additional ST-segment changes, which imply a poor prognosis, result either from ischemia in a territory other than the area of infarction, termed *ischemia at a distance*, or from reciprocal electrical phenomena. Much attention has been directed toward associated ST-segment depression in the anterior leads when it occurs in patients with acute inferior STEMI. Yet despite the clinical importance of differentiation among causes of anterior ST-segment depression in such patients, including anterior ischemia, inferolateral wall infarction, and true reciprocal changes, such differentiation cannot be made reliably by electrocardiographic or even

vector cardiographic techniques. Although precordial ST-segment depression is more commonly associated with extensive infarction of the lateral or inferior septal segments than with anterior wall subendocardial ischemia, imaging techniques such as echocardiography are necessary to ascertain whether an anterior wall motion abnormality is present.

Right Ventricular Infarction

ST-segment elevation in the right precordial leads (V_1 , V_3R through V_6R) is a relatively sensitive and specific sign of RV infarction.³¹ Occasionally, ST-segment elevation in leads V_2 and V_3 results from acute RV infarction; this appears to occur only when injury to the left inferior wall is minimal.⁹⁵ Usually, the concurrent inferior wall injury suppresses this anterior ST-segment elevation resulting from RV injury. Similarly, RV infarction appears to reduce the anterior ST-segment depression often observed with inferior wall MI. A QS or QR pattern in leads V_3R and/or V_4R also suggests RV myocardial necrosis but has less predictive accuracy than does ST-segment elevation in these leads.

Imaging

Noninvasive imaging provides important diagnostic and prognostic information in patients with MI. In most cases of STEMI, unless the ECG is nondiagnostic or the clinical scenario is questionable, imaging is not required for diagnosis—but imaging plays many roles after diagnosis, including determining the extent of the infarct, the presence of mechanical complications, and the overall function of the right and left ventricles.

Roentgenography (See Chapter 15)

The initial chest roentgenogram in patients with STEMI is almost invariably a portable film obtained in the emergency department or cardiac care unit. When present, prominent pulmonary vascular markings on the roentgenogram reflect elevated LV end-diastolic pressure, but significant temporal discrepancies can occur because of what have been termed *diagnostic lags* and *post-therapeutic lags*. Up to 12 hours can elapse before pulmonary edema accumulates after ventricular filling pressure has become elevated. The post-therapeutic phase lag represents a longer time interval; up to 2 days is required for pulmonary edema to be resorbed and the radiographic signs of pulmonary congestion to clear after ventricular filling pressure has returned toward normal. The degree of congestion and the size of the left side of the heart on the chest film are useful for defining groups of patients with STEMI who have an increased risk for fatal complications.

Echocardiography (See Chapter 14)

The relative portability of echocardiographic equipment makes this technique ideal for the assessment of patients with MI.⁹⁶ In patients with chest pain compatible with MI but with a nondiagnostic ECG, the finding on echocardiography of a distinct region of disordered contraction can support the diagnosis of myocardial ischemia. Echocardiography can also provide some help in evaluating patients with chest pain and a nondiagnostic ECG who are suspected of having aortic dissection. Identification of an intimal flap consistent with aortic dissection is a critical observation because the finding would drive critical changes in therapeutic strategy (see Chapter 57), but transthoracic echocardiography has poor sensitivity for detecting aortic dissection in comparison to other imaging modalities such as computed tomography (CT) angiography.

LV function estimated from echocardiograms correlates well with measurements from angiography and is useful in establishing the prognosis after MI.⁹⁶ Furthermore, early use of echocardiography can aid in early detection of potentially viable but stunned myocardium (contractile reserve), residual provokable ischemia, patients at risk for the development of congestive heart failure after MI, and mechanical complications of MI. Newer techniques also provide information regarding the success of myocardial tissue-level reperfusion.⁹⁷ Although transthoracic imaging is adequate in most patients, some patients have poor echocardiographic windows, especially if they are

undergoing mechanical ventilation. In such patients, transesophageal echocardiography can be performed safely and may help in evaluating ventricular septal defects and papillary muscle dysfunction.¹⁰

Doppler techniques allow assessment of blood flow in the cardiac chambers and across cardiac valves. When used in conjunction with echocardiography, Doppler interrogation can help in detecting and assessing the severity of mitral or tricuspid regurgitation after STEMI, the site of acute ventricular septal rupture, quantification of shunt flow across the resulting defect, and assessment of acute cardiac tamponade.¹⁰

Magnetic Resonance Imaging (See Chapter 17)

In addition to localizing and sizing the area of infarction, magnetic resonance imaging (MRI) techniques permit early recognition of MI and can provide an assessment of the severity of the ischemic insult. This modality is attractive because of its ability to assess perfusion of infarcted and noninfarcted tissue, as well as reperfused myocardium; to identify areas of jeopardized but not infarcted myocardium; to identify myocardial edema, fibrosis, wall thinning, and hypertrophy; to assess ventricular chamber size and segmental wall motion; and to identify the temporal transition between ischemia and infarction (Fig. 51-19).⁹⁸⁻¹⁰¹ MRI has limited application during the acute phase because of the need to transport patients with MI to the MRI

facility, but as discussed later, it is an extremely useful imaging technique during the subacute and chronic phases of MI.

Contrast-enhanced CMR with gadolinium can define areas of myocardial necrosis accurately. The transmural extent of late gadolinium enhancement (LGE) in regions of dysfunctional myocardium accurately predicts the likelihood of recovery of contractile function after successful restoration of coronary flow via mechanical revascularization.¹⁰² Numerous clinical studies have also demonstrated the high sensitivity of LGE (“delayed hyperenhancement”) of CMR in detecting small amounts of myonecrosis. LGE accurately identifies the infarct zone when compared with histologic examination. The best predictor of return to normal ventricular wall thickening is less than 25% transmural LGE. LGE is also a sensitive technique for detecting RV infarcts.⁹⁹

In patients with a previous MI, estimation of the size of the perinfarct zone by CMR with the delayed-enhancement technique provides incremental prognostic value beyond LV volume and ejection fraction. Besides detecting infarction, this imaging technique can characterize the presence and size of microvascular obstruction as a result of infarction, which may be an even poorer prognostic finding than LGE is. Clinically unrecognized myocardial scar detected by LGE imaging is associated with high risk for adverse cardiac events in patients with signs and symptoms of coronary artery disease but without a history of infarction.¹⁰⁰

Nuclear Imaging (See Chapter 16)

Radionuclide angiography, perfusion imaging, infarct-avid scintigraphy, and positron emission tomography can all be used to evaluate patients with STEMI.^{100,103} Nuclear cardiac imaging techniques can detect MI; assess infarct size, collateral flow, and jeopardized myocardium; determine the effects of the infarct on ventricular function; and establish the prognosis of patients with STEMI. Yet the necessity of moving a critically ill patient from the coronary care unit to the nuclear medicine department limits practical application.

Computed Tomography (See Chapter 18)

CT can provide an assessment of cavity dimensions and wall thickness, can detect LV aneurysms, and—of particular importance in patients with STEMI—can identify intracardiac thrombi. In the acute setting, contrast-enhanced CT detects focal areas of MI as decreased areas of enhancement. Older infarcts show hyperenhancement. Although cardiac CT is a less convenient technique, it is probably more sensitive than echocardiography for thrombus detection.¹⁰⁴ Coronary CT angiography is sensitive in detecting coronary obstructions, particularly in the proximal third of the coronary anatomy, and may improve the diagnostic evaluation of patients with a low to intermediate probability of ACS, but it does not have a role in the management of suspected STEMI.¹⁰⁵

FIGURE 51-19 Vertical long-axis delayed-enhancement MRI in a patient with extensive transmural anteroapical MI (A). Horizontal long-axis cine-MRI at baseline (B), at 4 months (C), and at 1 year (D) shows progressive LV dilation (LV end-diastolic volume index of 81.9 mL/m² at baseline, 88.2 mL/m² at 4 months, and 112.7 mL/m² at 1 year) with progressive thinning of the LV wall. (From Ganame J, Messalli G, Masci PG, et al: Time course of infarct healing and left ventricular remodeling in patients with reperfused STEMI using comprehensive magnetic resonance imaging. *Eur Radiol* 21:693, 2011.)

Estimation of Infarct Size

ELECTROCARDIOGRAPHY. Interest in limiting infarct size, largely because of the recognition that the quantity of infarcted myocardium has important prognostic implications, has focused attention on accurate determination of MI size. The sum of ST-segment elevations measured from multiple precordial leads correlates with the extent of myocardial injury in patients with anterior MI.⁹² Yet a relationship exists between the number of ECG leads showing ST-segment elevation and the mortality rate: patients with 8 or 9 of 12 leads showing ST-segment elevation have three to four times the mortality of those with only 2 or 3 leads demonstrating ST-segment elevation.

CARDIAC MARKERS. Estimation of infarct size by analysis of serum or plasma cardiac markers requires accounting for the quantity of the marker lost from the myocardium, its volume of distribution, and its release ratio. Serial measurements of proteins released by necrotic myocardium can be used to help determine MI size. Clinically, the peak CK, CK-MB, or troponin level provides an approximate estimate of infarct size. Coronary artery reperfusion dramatically changes the wash-out kinetics of necrosis markers from myocardium, thereby resulting in early and exaggerated peak levels (see Fig. 51-17). Measuring a cardiac-specific troponin level several days after STEMI, even in cases of successful reperfusion, may provide a reliable estimate of infarct size because such late troponin measurements reflect delayed release from the myofilament-bound pool in damaged myocytes.

NONINVASIVE IMAGING TECHNIQUES. The imaging modalities discussed above can aid in experimental and clinical assessment of infarct size. Echocardiography remains the most commonly used modality for assessing infarct size and LV function, although contrast-enhanced CMR can detect smaller degrees of ischemia and identify areas of injury that are permanently damaged myocardium versus “stunned” regions, which may recover. CMR can also discern the regional heterogeneity of infarction patterns in patients with persistently occluded infarct arteries or severe microvascular occlusion versus those with a successfully reperfused macrocirculation and microcirculation.¹⁰⁰

ACKNOWLEDGMENT

The authors wish to acknowledge the previous contributions of Dr. Elliott M. Antman, which have laid the foundation for this chapter.

The care of patients with ST-elevation myocardial infarction (STEMI) has transformed in conjunction with major shifts in the approach to reperfusion therapy from primarily pharmacologic to catheter-based strategies.¹⁻⁴ With simultaneous advances in medical therapy, the case fatality rate for patients with STEMI has continued to decline.⁵ Nevertheless, optimal management of patients at high risk for or with established major complications of STEMI remains critical to the care of this condition. A discussion of the management of STEMI can follow the clinical course of the patient. **Chapter 42** addresses primary and secondary prevention of coronary artery disease (CAD). This chapter deals with treatment at the time of onset of STEMI (prehospital issues, initial recognition and management in the emergency department, and reperfusion), hospital management (medications, complications, and preparation for discharge), and early secondary prevention after STEMI. **Chapter 55** discusses percutaneous coronary intervention (PCI) in patients with STEMI. **Chapter 36** describes the use of internal and external automated defibrillators for primary prevention of sudden cardiac death after myocardial infarction (MI).

PREHOSPITAL MANAGEMENT

Given the progressive loss of functioning myocytes with persistent occlusion of the infarct-related artery in STEMI (**see Chapter 51**), initial management aims to restore blood flow to the infarct zone as rapidly as possible. Primary PCI (**see Chapter 55**) is generally the preferred option, provided that an experienced operator and team can perform it in timely fashion.^{1,6,7} Missed opportunities for improvement in the care of STEMI include failure to deliver any form of reperfusion therapy in approximately 20% of patients and failure to minimize delays in reperfusion because of inefficient systems of care.^{5,8,9} The “chain of survival” for STEMI involves a highly integrated strategy beginning with patient education about the symptoms of MI (**see Chapter 50**) and early contact with the medical system, coordination of destination protocols in emergency medical service (EMS) systems, efficient practices in emergency departments to shorten door-to-reperfusion time, and expeditious implementation of the reperfusion strategy by a trained team.^{10,11} The American Heart Association (AHA) launched a national initiative to engineer

improved health care delivery for STEMI, including implementation of systems that shorten total ischemic time (**Tables 52-1 and 52-2**) while emphasizing overall quality of care for STEMI.^{11,12}

Prehospital Care

The prehospital care of patients suspected of having STEMI bears directly on the likelihood of survival. Most deaths associated with STEMI occur within the first hour of its onset and usually result from ventricular fibrillation (VF) (**see Chapter 39**). Hence immediate implementation of resuscitative efforts and rapid transportation of the patient to a hospital have prime importance. Major components of the delay from the onset of ischemic symptoms to reperfusion include the following¹: (1) the time for the patient to recognize the seriousness of the problem and seek medical attention; (2) prehospital evaluation, treatment, and transportation; (3) the time for diagnostic measures and initiation of treatment in the hospital (e.g., “door-to-needle” time for patients receiving a fibrinolytic agent and “door-to-balloon” time for patients undergoing a catheter-based reperfusion strategy); and (4) the time from initiation of treatment to restoration of flow.

Patient-related factors that correlate with a longer time until deciding to seek medical attention include older age; female sex; black race; low socioeconomic status; low emotional or somatic awareness; history of angina, diabetes, or both; consulting a spouse or other relative; and consulting a physician.^{13,14} Health care professionals should heighten the level of awareness of patients at risk for STEMI (e.g., those with hypertension, diabetes, history of angina pectoris).¹ They should use each patient encounter as a “teachable moment” to review and reinforce with patients and their families the need to seek urgent medical attention for a pattern of symptoms that includes chest discomfort, extreme fatigue, and dyspnea, especially if accompanied by diaphoresis or lightheadedness. Patients should also be instructed in the proper use of sublingual nitroglycerin and to call emergency services if the ischemic-type discomfort persists for more than 5 minutes.¹

Emergency Medical Service Systems

EMS systems have three major components: emergency medical dispatch, first response, and the EMS ambulance response. The

expanded capability to record a prehospital 12-lead electrocardiogram (ECG) represents a major advance in EMS systems (Table 52-2).¹⁵ The ability to transmit such ECGs and to activate the STEMI care team before arrival at the hospital places EMS efforts at the center of the early response to STEMI.^{16,17} Ongoing efforts to shorten the time until treatment of patients with STEMI include improvement in the medical dispatch component by expanding 911 coverage,

providing automated external defibrillators to first responders, placing automated external defibrillators in critical public locations, and greater coordination of the EMS ambulance response. Well-equipped ambulances and helicopters staffed by personnel trained in the acute care of patients with STEMI allow definitive therapy to begin during transport to the hospital (Table 52-3). Radiotelemetry systems that allow transmission of the electrocardiographic signal to a medical control officer are highly desirable for facilitating the triage of patients with STEMI and are becoming increasingly available in many communities (Fig. 52-1).

In addition to prompt defibrillation, the efficacy of prehospital care appears to depend on several factors, including early relief of pain with its deleterious physiologic sequelae, reduction of excessive

TABLE 52-1 Criteria for a System of Care for ST-Elevation Myocardial Infarction

1. The system should be registered with Mission: Lifeline.
2. Ongoing multidisciplinary team meetings should occur, including EMS, non-PCI hospitals/STEMI referral centers, and PCI hospitals/STEMI receiving centers, to evaluate outcomes and quality improvement data. Operational issues should be reviewed, problems identified, and solutions implemented.
3. Each STEMI system should include a process for prehospital identification and activation, destination protocols to STEMI receiving centers, and transfer for patients who arrive at STEMI referral centers and are primary PCI candidates, are ineligible for fibrinolytic therapy, and/or are in cardiogenic shock.
4. Each system should have a recognized system coordinator, physician champion, and EMS medical director.
5. Each system component (EMS, STEMI referral centers, and STEMI receiving centers) should meet the appropriate criteria (see www.americanheart.org/missionlifeline).

Modified from www.americanheart.org/missionlifeline.

TABLE 52-2 Interventions to Improve Door-to-Device Times

1. A prehospital ECG for diagnosing STEMI is used to activate the PCI team while the patient is en route to the hospital.
2. Emergency physicians activate the PCI team.
3. A single call to a central page operator activates the PCI team.
4. A goal is set for the PCI team to arrive at the catheterization laboratory within 20 minutes after being paged.
5. Timely data feedback and analysis are provided to members of the STEMI care team.

TABLE 52-3 Prehospital* Reperfusion Checklist for Evaluation of Patients with ST-Elevation Myocardial Infarction

Step 1:		
Has the patient experienced chest discomfort for >15 min and <12 hr?		
YES	NO	
	STOP	
Step 2:		
Are there contraindications to fibrinolysis? If any of the following are checked, fibrinolysis may be contraindicated.		
Systolic blood pressure >180 mm Hg	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Diastolic blood pressure >110 mm Hg	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Difference in systolic blood pressure in the right versus the left arm >15 mm Hg	<input type="checkbox"/> YES	<input type="checkbox"/> NO
History of structural central nervous system disease	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Significant closed head/ facial trauma within the previous 3 months	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Recent (within 6 weeks) major trauma, surgery (including laser eye surgery), gastrointestinal or genitourinary bleeding	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Bleeding or clotting problem while taking blood thinners	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Cardiopulmonary resuscitation longer than 10 minutes	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Pregnant female	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Serious systemic disease (e.g., advanced/terminal cancer, severe liver or kidney disease)	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Step 3:		
Does the patient have severe heart failure or cardiogenic shock such that PCI is preferable?		
Pulmonary edema (rales greater than halfway up)	<input type="checkbox"/> YES	<input type="checkbox"/> NO
Systemic hypoperfusion (cold, clammy)	<input type="checkbox"/> YES	<input type="checkbox"/> NO

*Note that some of these practical criteria for a prehospital checklist are more inclusive than may subsequently be applied in the hospital if using more refined criteria that differ slightly from the above (see Table 52-4).

From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). *Circulation* 110(9):e82, 2004.

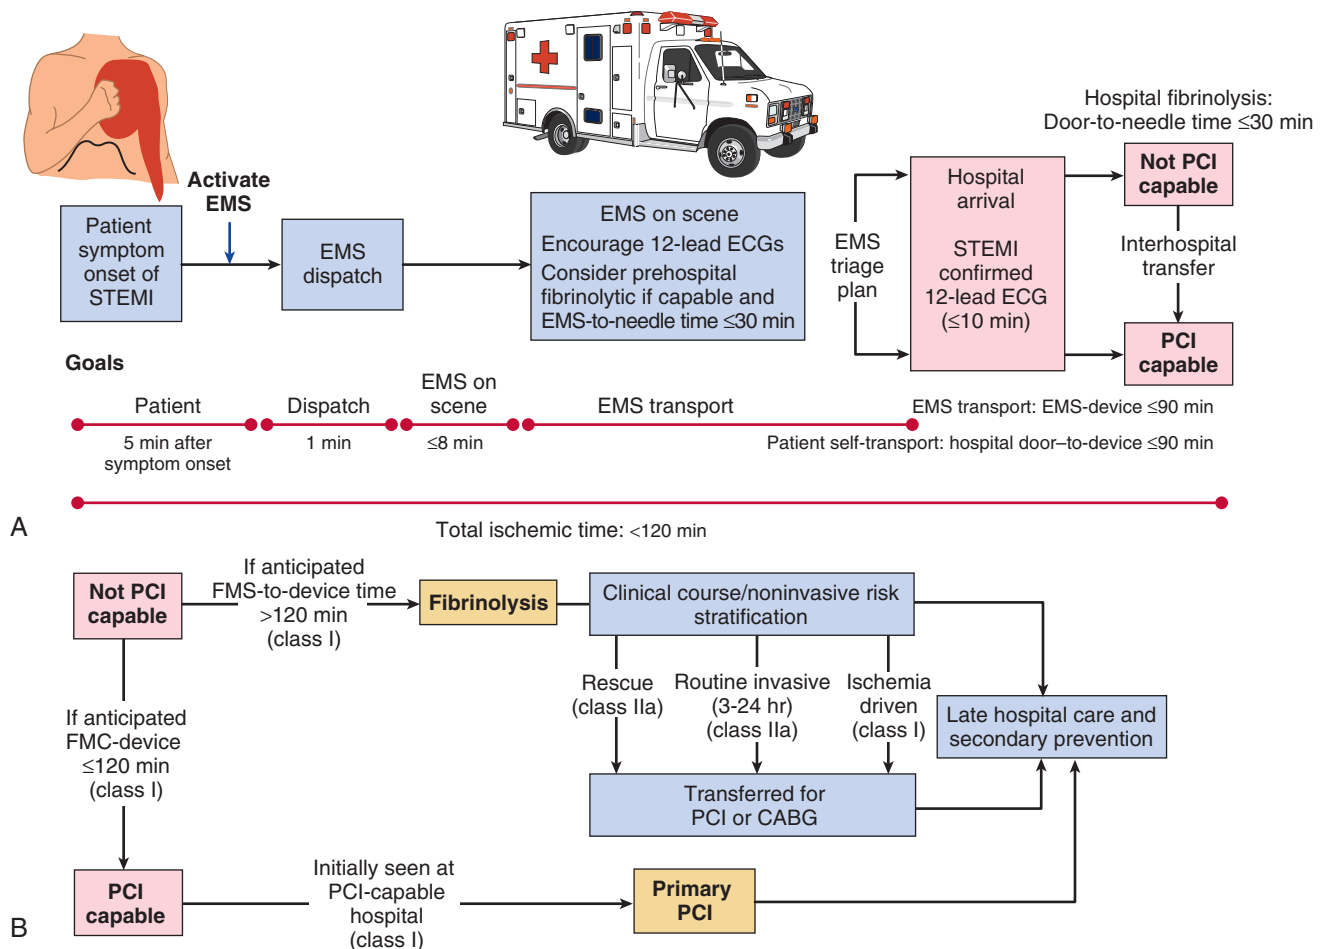

FIGURE 52-1 System goals and initial reperfusion treatment of patients with STEMI. Reperfusion in patients with STEMI can be accomplished by pharmacologic (fibrinolysis) or catheter-based (primary PCI) approaches and may involve transfer from a non-PCI-capable to a primary PCI-capable center. **A**, Patient transported by the EMS. The STEMI systems goal is to maintain a network of transportation and destination hospitals so that the total ischemic time is kept to less than 120 minutes. In addition to this overall goal, three additional time objectives exist. (1) If the EMS has fibrinolytic capability and the patient qualifies for therapy, prehospital fibrinolysis may be considered and, if used, should be started within 30 minutes of arrival of the EMS on scene. (2) For patients transported to a non-PCI-capable hospital where a fibrinolytic is to be administered, the hospital door-to-needle time should be 30 minutes or less. (3) If the patient is transported to a PCI-capable hospital, the time from first medical contact (FMC) to deployment of the first PCI device (FMC-to-device time) should be 90 minutes or less. Patient self-transportation is discouraged. If the patient arrives at a non-PCI-capable hospital and a fibrinolytic is to be administered, the door-to-needle time should be 30 minutes or less. If the patient arrives at a PCI-capable hospital, the door-to-balloon time should be 90 minutes or less. The treatment options and time recommendations after arrival at the hospital are the same. Consideration of emergency interhospital transfer of the patient to a PCI-capable hospital for mechanical revascularization is also appropriate if use of a fibrinolytic is contraindicated or PCI can be initiated promptly (anticipated FMC-to-device time ≤ 120 minutes) or if fibrinolysis is unsuccessful (i.e., “rescue PCI”). Secondary nonemergency interhospital transfer can be considered for recurrent ischemia or routine invasive evaluation 3 to 24 hours after fibrinolysis. **B**, Reperfusion strategies for patients with STEMI, regardless of whether they go to a PCI-capable or to a non-PCI-capable hospital. The optimal strategy depends on the timing of the onset of symptoms, the patient’s eligibility for fibrinolysis, and the options for timely transfer to a PCI-capable hospital. The denoted class I and class II recommendations are from the ACCF/AHA guidelines for the management of STEMI. For patients who receive fibrinolysis, noninvasive risk stratification is recommended to guide decisions regarding delayed coronary revascularization. (Modified from Armstrong PW, Colen D, Antman E: Fibrinolysis for acute myocardial infarction: The future is here and now. *Circulation* 107:2533, 2003; and O’Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e78, 2013.)

activity of the autonomic nervous system, and treatment of arrhythmias such as ventricular tachycardia (VT)—but these efforts must not delay rapid transfer to the hospital (Fig. 52-1).

Prehospital Fibrinolysis

Multiple observational studies and several randomized trials have evaluated the potential benefits of prehospital versus in-hospital fibrinolysis.^{1,17} Although none of the individual trials showed a significant reduction in mortality with prehospital-initiated fibrinolytic therapy, earlier treatment generally provides greater benefit: a meta-analysis of all the available trials demonstrated a 17% reduction in mortality.¹ The CAPTIM (Comparison of primary Angioplasty and Pre-hospital fibrinolysis In acute Myocardial infarction) trial, for example, reported a trend toward a lower mortality rate in patients with STEMI who received prehospital fibrinolysis than in those who received primary PCI, especially if they were treated within 2 hours of the onset of

symptoms.¹ Prehospital fibrinolysis is reasonable in settings in which substantial time can be saved by prehospital treatment because of long transportation times (i.e., 60 to 90 minutes or longer), physicians are present in the ambulance, or there is a well-organized EMS system with full-time paramedics who can obtain and transmit 12-lead electrocardiographic recordings from the field to an online medical command able to authorize prehospital fibrinolysis (Fig. 52-1).¹⁸

MANAGEMENT IN THE EMERGENCY DEPARTMENT

When evaluating patients with chest pain in the emergency department, physicians must confront the difficult tasks of rapidly identifying patients who require urgent reperfusion therapy, triaging lower-risk patients to the appropriate setting within the hospital, and

not discharging patients inappropriately while avoiding unnecessary admissions. A history of ischemic-type discomfort and the initial 12-lead ECG are the primary tools for screening patients with possible acute coronary syndromes (ACSs) for STEMI (see Chapter 50).¹⁹ Because the 12-lead ECG is at the center of the decision pathway for initiation of reperfusion therapy, it should be obtained promptly (≤ 10 minutes after hospital arrival) in patients with ischemic discomfort.¹ More extensive use of prehospital 12-lead ECGs has also facilitated early triage of patients with STEMI.¹⁵ Because lethal arrhythmias can occur suddenly in patients with STEMI, all patients should have bedside monitoring of the ECG and intravenous access.

The presence of ST-segment elevation on the ECG in a patient with ischemic discomfort highly suggests thrombotic occlusion of an epicardial coronary artery, and it should trigger a well-rehearsed sequence of rapid assessment of the patient for initiation of a reperfusion strategy.¹ If the initial ECG reveals ST-segment elevation of 0.1 mV or greater in at least two contiguous leads or a new or presumably new left bundle branch block, the patient should be evaluated immediately for a reperfusion strategy. Critical factors that weigh into selection of a reperfusion strategy include the time elapsed since the onset of symptoms, the risk associated with STEMI, the risk related to administering a fibrinolytic, and the time required to initiate an invasive strategy (Fig. 52-1). In non-PCI-capable hospitals, the initial assessment should include evaluation of the contraindications to administration of a fibrinolytic (Table 52-4). Patients with an initial ECG that reveals new or presumably new ST-segment depression and/or T wave inversion without ST-segment elevation are not considered candidates for immediate reperfusion therapy unless a posterior injury current is suspected (see Chapter 53).

Given the importance of time to reperfusion,⁷ emphasis has shifted to overall medical system goals, starting at the point of first medical

contact with the patient.^{1,20} Benchmarks for medical systems to use when assessing the quality of their performance are a door-to-needle time of 30 minutes or less for initiation of fibrinolytic therapy and a door-to-device time of 90 minutes or less for percutaneous coronary perfusion (Fig. 52-1).^{1,4}

In patients with a clinical history suggestive of STEMI (see Chapter 50) and an initial nondiagnostic ECG (i.e., no ST-segment deviation or T wave inversion), serial tracings should be obtained during evaluation in the emergency department. Emergency department staff can seek the sudden development of ST-segment elevation by periodic visual inspection of the bedside electrocardiographic monitor, by continuous ST-segment recording, or by auditory alarms when the ST-segment deviation exceeds programmed limits. Decision aids such as computer-based diagnostic algorithms, identification of high-risk clinical indicators, rapid determination of cardiac biomarkers, echocardiographic evaluation for regional wall motion abnormalities, and myocardial perfusion imaging have greatest clinical usefulness when the findings on the ECG are not diagnostic.

General Treatment Measures

Aspirin (See also Chapter 82)

Aspirin is effective across the entire ACS spectrum and is part of the initial management strategy for patients with suspected STEMI. Because low doses take several days to achieve a full antiplatelet effect, 162 to 325 mg should be administered at the first opportunity after initial medical contact.¹ To achieve therapeutic blood levels rapidly, the patient should chew the tablet to promote buccal absorption rather than absorption through the gastric mucosa.²¹

Control of Cardiac Pain

Initial management of patients with STEMI should target relief of pain and its associated heightened sympathetic activity. Control of cardiac pain is typically achieved with a combination of analgesics (e.g., morphine) and interventions to favorably improve the balance of myocardial oxygen supply and demand, including oxygen, nitrates, and in appropriately selected patients, beta-adrenergic receptor-blocking agents (beta blockers).¹

ANALGESICS. Although a wide variety of analgesic agents—including meperidine, pentazocine, and morphine—have been used to treat the pain associated with STEMI, morphine remains the drug of choice, except in patients with well-documented morphine hypersensitivity. Doses of 4 to 8 mg administered intravenously and doses of 2 to 8 mg repeated at intervals of 5 to 15 minutes have been recommended¹ until the pain is relieved or side effects emerge—hypotension, depression of respiration, or severe vomiting—that preclude further administration of the drug. Appropriate dosing of morphine sulfate will vary, however, depending on the patient's age, body size, blood pressure, and heart rate.

Reduction of anxiety with successful analgesia diminishes the patient's restlessness and the activity of the autonomic nervous system, with a consequent reduction in the heart's metabolic demands. Morphine has beneficial effects in patients with pulmonary edema caused by peripheral arterial and venous dilation (particularly in those with excessive sympathoadrenal activity); it reduces the work of breathing and slows the heart rate secondary to combined withdrawal of sympathetic tone and augmentation of vagal tone. Observational studies have identified an association between the administration of morphine and adverse outcomes in patients with ACSs; however, it is challenging to disentangle this observation from confounding by indication.

Maintaining the patient in a supine position and elevating the lower extremities if blood pressure falls can minimize hypotension following the administration of nitroglycerin and morphine. Such positioning is undesirable in patients with pulmonary edema, but morphine rarely produces hypotension in these circumstances. Administration of atropine intravenously may be helpful in treating the excessive vagomimetic effects of morphine.

NITRATES. By virtue of their ability to enhance coronary blood flow by coronary vasodilation and to decrease ventricular preload by increasing venous capacitance, sublingual nitrates are indicated for

TABLE 52-4 Contraindications to and Cautions in the Use of Fibrinolytics for Treating ST-Elevation Myocardial Infarction*

Absolute Contraindications
Any previous intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known malignant intracranial neoplasm (primary or metastatic)
Ischemic stroke within 3 months except acute ischemic stroke within 4.5 hours
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed-head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Severe uncontrolled hypertension (unresponsive to emergency therapy)
For streptokinase, previous treatment within the previous 6 months
Relative Contraindications
History of chronic, severe, poorly controlled hypertension
Significant hypertension at initial evaluation (SBP > 180 mm Hg or DBP > 110 mm Hg) [†]
History of previous ischemic stroke >3 months
Dementia
Known intracranial pathology not covered in Absolute Contraindications
Traumatic or prolonged (>10 minutes) cardiopulmonary resuscitation
Major surgery (<3 weeks)
Recent (within 2 to 4 weeks) internal bleeding
Noncompressible vascular punctures
Pregnancy
Active peptic ulcer
Oral anticoagulant therapy

*Viewed as advisory for clinical decision making and may not be all-inclusive or definitive.

[†]Could be an absolute contraindication in low-risk patients with MI.

DBP = diastolic blood pressure; SBP = systolic blood pressure.

From O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e78, 2013.

most patients with an ACS. At present, the only groups of patients with STEMI in whom sublingual nitroglycerin should *not* be given are those with suspected right ventricular infarction²² or marked hypotension (e.g., systolic pressure <90 mm Hg), especially if accompanied by bradycardia.

Once hypotension is excluded, a sublingual nitroglycerin tablet should be administered and the patient observed for improvement in symptoms or change in hemodynamics. If an initial dose is well tolerated and appears to be beneficial, further nitrates should be administered while monitoring vital signs. Even small doses can produce sudden hypotension and bradycardia, a reaction that can usually be reversed with intravenous atropine. Long-acting oral nitrate preparations should be avoided in the early course of STEMI because of the frequently changing hemodynamic status of the patient. In patients with a prolonged period of waxing and waning chest pain, intravenous nitroglycerin may help control the symptoms and correct the ischemia, but frequent monitoring of blood pressure is required. Initiation of a reperfusion strategy in patients with STEMI should not be delayed while assessing the patient's response to sublingual or intravenous nitrates.

BETA-ADRENERGIC BLOCKING AGENTS. These drugs aid in the relief of ischemic pain, reduce the need for analgesics in many patients, and reduce infarct size and life-threatening arrhythmias. Avoiding early intravenous blockade in patients with Killip class II or greater is important, however, because of the risk of precipitating cardiogenic shock.¹ Routine use of intravenous beta blockers is no longer recommended in patients with STEMI, but administration of a beta blocker intravenously at the initial evaluation of patients with STEMI who are hypertensive and have ongoing ischemia is reasonable.¹

A practical protocol for use of a beta blocker in this situation is as follows. (1) Exclude patients with heart failure, hypotension (systolic blood pressure <90 mm Hg), bradycardia (heart rate <60 beats/min), or significant atrioventricular (AV) block. (2) Administer metoprolol in three 5-mg intravenous boluses. (3) Observe the patient for 2 to 5 minutes after each bolus, and if the heart rate falls below 60 beats/min or systolic blood pressure falls below 100 mm Hg, do not administer any further drug. (4) If hemodynamic stability continues 15 minutes after the last intravenous dose, begin oral metoprolol tartrate, 25 to 50 mg every 6 hours for 2 to 3 days as tolerated, and then switch to 100 mg twice daily.¹ Lower doses may be used in patients who have a partial decline in blood pressure with the initial dosing or who appear to be at higher risk (e.g., larger infarction) for the development of heart failure because of poor left ventricular performance. Infusion of an extremely short-acting beta blocker, such as esmolol, 50 to 250 mg/kg/min, may be useful in patients with relative contraindications to the administration of a beta blocker and in whom slowing of the heart rate is considered highly desirable.²³

OXYGEN. Hypoxemia can occur in patients with STEMI and generally results from ventilation-perfusion abnormalities that are sequelae of left ventricular failure; concomitant intrinsic pulmonary disease may be an additional cause of hypoxemia. Treating all patients hospitalized for STEMI with oxygen for at least 24 to 48 hours is common practice based on the empiric assumption of hypoxia and evidence that increased oxygen in the inspired air may protect ischemic myocardium. However, augmentation of the fraction of oxygen in the inspired air does not elevate oxygen delivery significantly in patients who are not hypoxemic. Furthermore, it may increase systemic vascular resistance and arterial pressure and thereby lower cardiac output slightly.

In view of these considerations, arterial oxygen saturation can be estimated by pulse oximetry, and oxygen therapy can be omitted if the oximetric findings are normal. On the other hand, patients with STEMI and arterial hypoxemia should receive oxygen.¹ In patients with severe pulmonary edema, endotracheal intubation and mechanical ventilation may be necessary to correct the hypoxemia and reduce the work of breathing.

Limitation of Infarct Size

Infarct size is an important determinant of prognosis in patients with STEMI. Patients who succumb from cardiogenic shock generally

exhibit either a single massive infarct or a small to moderate infarct superimposed on multiple previous infarctions.^{24,25} Survivors with large infarcts frequently exhibit late impairment of ventricular function, and their long-term mortality rate is higher than that of survivors with small infarcts, in whom cardiac decompensation tends not to develop.²⁶ In view of the prognostic importance of infarct size, the possibility of modifying infarct size has attracted much experimental and clinical attention (see Chapter 51, Fig. 51-11).^{7,27} Efforts to limit infarct size have been divided among several different (sometimes overlapping) approaches: (1) early reperfusion, (2) reduction of myocardial energy demands, (3) manipulation of energy production sources in the myocardium, and (4) prevention of reperfusion injury.

Dynamic Nature of Infarction

STEMI is a dynamic process that does not occur instantaneously but rather evolves over a period of hours. The fate of jeopardized, ischemic tissue can be favorably affected by interventions that restore myocardial perfusion, reduce microvascular damage in the infarct zone, decrease myocardial oxygen requirements, inhibit accumulation or facilitate washout of noxious metabolites, augment the availability of substrate for anaerobic metabolism, or blunt the effects of mediators of injury that compromise the structure and function of intracellular organelles and constituents of cell membranes. Strong evidence in experimental animals and suggestive evidence in patients indicate that ischemic preconditioning, a form of endogenous protection against STEMI, before sustained coronary occlusion decreases infarct size and is associated with a more favorable outcome along with decreased risk for extension of infarction and recurrent ischemic events. Brief episodes of ischemia in one coronary vascular bed may precondition myocardium in a remote zone and thereby attenuate the size of infarction in the latter when sustained coronary occlusion occurs.²⁸

Perfusion of myocardium in the infarct zone appears to be reduced maximally immediately following coronary occlusion. Spontaneous recanalization of an occluded infarct-related artery occurs in up to a third of patients beginning at 12 to 24 hours. This delayed spontaneous reperfusion may enhance left ventricular function because it improves healing of infarcted tissue, prevents ventricular remodeling, and reperfuses hibernating myocardium. Yet, strategies involving pharmacologically induced and catheter-based reperfusion of the infarct vessel can *maximize* the amount of salvaged myocardium by *accelerating* the process of reperfusion and also implementing it in patients who would otherwise have an occluded infarct-related artery (Fig. 52-1) (see Chapter 55). An overarching concept that applies to all methods of reperfusion is the critical importance of time. Reduction of mortality in patients with STEMI is greatest the earlier the infarct artery is reperfused (Fig. 52-2).¹

Additional factors that may limit infarct size during reperfusion include relief of coronary spasm, prevention of damage to the microvasculature, improved systemic hemodynamics (augmentation of coronary perfusion pressure and reduced left ventricular end-diastolic pressure), and collateral circulation. Prompt implementation of measures designed to protect ischemic myocardium and support myocardial perfusion may provide sufficient time for the development of compensatory mechanisms that limit the ultimate extent of infarction (see Chapter 51). Interventions designed to protect ischemic myocardium during the initial event may also reduce the extension of infarction or early reinfarction.

Routine Measures for Limitation of Infarct Size

Although timely reperfusion of ischemic myocardium is the most important technique for limiting infarct size, several routine measures to accomplish this goal apply to all patients with STEMI, regardless of whether they receive reperfusion therapy.¹ The treatment strategies discussed in this section can be initiated at first medical contact and be continued throughout the hospital phase of care.

Myocardial oxygen consumption should be minimized by maintaining the patient at rest both physically and emotionally and by using mild sedation and a quiet atmosphere—in addition to the interventions already discussed. Administration of adrenergic agonists

should be avoided whenever possible. All forms of tachyarrhythmia require prompt treatment because they increase myocardial oxygen needs. Heart failure should also be treated swiftly to minimize increases in adrenergic tone and hypoxemia (see the section [Left Ventricular Failure](#)).

FIGURE 52-2 The reduction in mortality as a benefit of reperfusion therapy is greatest in the first 2 to 3 hours after the onset of symptoms of acute MI, most likely a consequence of myocardial salvage. The exact duration of this critical early period may be modified by several factors, including the presence of functioning collateral coronary arteries, ischemic preconditioning, myocardial oxygen demands, and the duration of sustained ischemia. After this early period the magnitude of the mortality benefit is much reduced, and as the mortality reduction curve flattens, time to reperfusion therapy is less critical. The magnitude of the benefit depends on how far up the curve that the patient can be shifted. The benefit of a shift from point A or B to point C would be substantial, but the benefit of a shift from point D to point B would be small. This schematic illustrates how a treatment strategy that delays therapy during the early critical period, such as transfer of a patient for PCI with a long transportation time, could be harmful (shift from point D to point C or point B). (Modified from Gersh BJ, Stone GW, White HD, Holmes DR Jr: Pharmacological facilitation of primary percutaneous coronary intervention for acute myocardial infarction: Is the slope of the curve the shape of the future? *JAMA* 293:979, 2005.)

FIGURE 52-3 Importance of time to reperfusion in patients undergoing fibrinolysis (A) or primary PCI (B) for STEMI. **A**, Graph based on data from 85,589 patients treated with fibrinolysis. A progressive increase in the in-hospital mortality rate occurs for every 30-minute delay. **B**, Based on data from 43,801 patients, this graph depicts the adjusted in-hospital mortality rate as a function of door-to-balloon time. Estimated mortality ranged from 3% with a door-to-balloon time of 30 minutes to 10.3% in patients with a door-to-balloon time of 240 minutes. (Data from Cannon CP, Gibson CM, Lambrew CT, et al: Relationship of symptom-onset-to-balloon time and door-to-balloon time with mortality in patients undergoing angioplasty for acute myocardial infarction. *JAMA* 283:2941, 2000; and Rathore SS, Curtis J, Chen J, et al: Association of door-to-balloon time and mortality in patients admitted to hospital with ST elevation myocardial infarction: National cohort study. *BMJ* 338:b1807, 2009.)

If ongoing ischemia occurs, severe anemia should be corrected by the cautious administration of packed red blood cells, accompanied by a diuretic if there is any evidence of left ventricular failure. Associated conditions, particularly infections and accompanying tachycardia, fever, and elevated myocardial oxygen needs, require management.

REPERFUSION THERAPY

General Concepts

Although late spontaneous reperfusion occurs in some patients, thrombotic occlusion persists in most patients with STEMI. Timely reperfusion of jeopardized myocardium is the most effective way of restoring the balance between myocardial oxygen supply and demand.²⁹ The dependence of myocardial salvage on the time elapsed until treatment pertains to patients treated with either fibrinolysis or PCI.^{30,31} (Fig. 52-3; also see Fig. 52-2). The efficacy of fibrinolytic agents decreases as coronary thrombi mature over time (Fig. 52-3). Analyses adjusted for baseline risk, however, demonstrate a statistically significant increase in in-hospital and long-term mortality with progressive delays between the onset of symptoms and PCI.^{30,32} Each 30-minute delay from symptom onset to PCI increases the relative risk (RR) for 1-year mortality by 8%.¹

In some patients, particularly those with cardiogenic shock, tissue damage occurs in a “stuttering” manner rather than abruptly. This concept of the infarction process, as well as the observation that the incidence of complications of STEMI in both the early and late postinfarction periods depends on infarct size, underscores the need for careful history taking to ascertain whether the patient appears to have had repetitive cycles of spontaneous reperfusion and reocclusion. Determining the precise time of onset of the infarction process in these patients, however, can be difficult and sometimes misleading. In such patients with waxing and waning ischemic discomfort, a rigid time interval from the first episode of pain should not be used when determining whether a patient is “outside the window” for benefit from acute reperfusion therapy.

Pathophysiology of Myocardial Reperfusion

Prevention of cell death by restoration of blood flow depends on the severity and duration of the preexisting ischemia. Substantial experimental and clinical evidence indicates that the earlier blood flow is restored, the more favorably influenced are recovery of left ventricular systolic function, improvement in diastolic function, and reduction in overall mortality.¹ Collateral coronary vessels also appear to influence left ventricular function following reperfusion.³³ They provide sufficient perfusion of myocardium to slow cell death and probably have greater importance in patients undergoing reperfusion later than 1 to 2 hours after coronary occlusion. Even after successful reperfusion and despite the absence of irreversible myocardial damage, a period of postischemic contractile dysfunction can occur—a phenomenon referred to as *myocardial stunning*.³⁴

Reperfusion Injury

The process of reperfusion, although beneficial in terms of myocardial salvage, may be accompanied by adverse sequelae described by the term *reperfusion injury* (see Chapter 51).^{35,36} Several types of reperfusion injury occur in experimental animals: (1) lethal reperfusion injury, which refers to reperfusion-induced death of cells that were still viable at the time of

restoration of coronary blood flow; (2) vascular reperfusion injury, which is progressive damage to the microvasculature such that there is an expanding area of no-reflow and loss of coronary vasodilatory reserve; (3) stunned myocardium, in which salvaged myocytes display a prolonged period of contractile dysfunction following restoration of blood flow because of abnormalities in intracellular metabolism leading to reduced energy production; and (4) reperfusion arrhythmias, which refers to bursts of VT (and on occasion, VF) that occur within seconds of reperfusion.³⁷ Evidence suggests that vascular reperfusion injury, stunning, and reperfusion arrhythmias can all occur in patients with STEMI. The concept of lethal reperfusion injury to potentially salvageable myocardium remains controversial, both in animals and in humans.^{36,38,39}

Microvasculature damage in the reperfused myocardium can lead to a hemorrhagic infarct (see Chapter 51). Fibrinolytic therapy appears more likely than catheter-based reperfusion to produce hemorrhagic infarction. Although concern has been raised that this hemorrhage may lead to extension of the infarct, such does not appear to be the case. Histologic study of patients not surviving despite successful reperfusion has revealed hemorrhagic infarcts, but this hemorrhage does not usually extend beyond the area of necrosis.

Protection Against Reperfusion Injury

A variety of adjunctive therapies have been proposed to mitigate the injury that occurs after reperfusion, including preservation of microvascular integrity by using antiplatelet agents and antithrombins to minimize embolization of atheroembolic debris, prevention of inflammatory damage, and metabolic support of the ischemic myocardium.^{36,39,40} The effectiveness of interventions directed against reperfusion injury appears to decline rapidly the later that they are administered after reperfusion. In animal models, no beneficial effect is detectable after 45 to 60 minutes of reperfusion has elapsed. Intriguingly, the phenomenon of induction of transient ischemia in other vascular beds has also been associated with a reduction in reperfusion injury, a concept called *remote conditioning*.²⁸

An alternative experimental approach to protection against reperfusion injury is called *postconditioning*, which involves introducing brief, repetitive episodes of ischemia alternating with reperfusion.⁴¹ This appears to activate the cellular protective mechanisms centering around prosurvival kinases.⁴² Many of these protective kinases are also activated during ischemic preconditioning. Clinical studies in patients with STEMI undergoing PCI have provided evidence that postconditioning protects the human heart and is associated with reduced infarct size and improvement in myocardial perfusion.⁴³

Reperfusion Arrhythmias

Transient sinus bradycardia occurs in many patients with inferior infarcts at the time of acute reperfusion, often accompanied by some degree of hypotension. This combination of hypotension and bradycardia with a sudden increase in coronary flow may involve activation of the Bezold-Jarisch reflex.⁴⁴ Premature ventricular contractions, accelerated idioventricular rhythm, and nonsustained VT also commonly follow successful reperfusion. Although some investigators have postulated that early afterdepolarizations participate in the genesis of reperfusion-related ventricular arrhythmias, they are present during both ischemia and reperfusion and therefore not likely to be involved in the development of reperfusion-associated VT or VF.

When present, rhythm disturbances may actually indicate successful restoration of coronary flow, but their specificity for successful reperfusion is limited. In general, clinical features are inaccurate markers of reperfusion, with no single clinical finding or constellation of findings being reliably predictive of angiographically demonstrated coronary artery patency.¹

Although reperfusion arrhythmias may show a temporal clustering at the time of restoration of coronary blood flow in patients after successful fibrinolysis, this brief “electrical storm” is generally innocuous, and therefore no prophylactic antiarrhythmic therapy is necessary and specific treatment is not indicated, except in rare cases of symptomatic or hemodynamically significant reperfusion arrhythmias.¹

Late Establishment of Patency of the Infarct Vessel

The improved survival and ventricular function after successful reperfusion may not result entirely from limitation of infarct size.⁴⁵ Poorly contracting or noncontracting myocardium in a zone that is supplied by a stenosed infarct-related artery with slow anterograde perfusion may still contain viable myocytes. The function of so-called *hibernating myocardium* can be improved by PCI to augment flow in the infarct-related artery.^{46,47}

Summary of the Effects of Myocardial Reperfusion

Disruption of plaque in the culprit vessel and subsequent thrombus formation produces complete occlusion of the infarct-related coronary artery. STEMI occurs with the ensuing development of left ventricular dilation and ultimately cell death through a combination of pump failure and electrical instability (see Chapter 51). Early reperfusion shortens the duration of coronary occlusion, minimizes the degree of ultimate left ventricular dysfunction and dilation, and reduces the probability that pump failure or malignant ventricular tachyarrhythmias will develop in patients with STEMI. Late reperfusion of stenosed infarct arteries may also restore contractile function in hibernating myocardium.

Fibrinolysis

Fibrinolysis recanalizes the thrombotic occlusion associated with STEMI, and restoration of coronary flow reduces infarct size and improves myocardial function and survival over both the short and long term.⁴⁸ Patients treated within the first 1 to 2 hours after the onset of symptoms seem to have the greatest potential for long-term improvement in survival with fibrinolysis.¹

Assessment of Reperfusion

TIMI Flow Grade. To provide a level of standardization both for clinical communication and for studies comparing various reperfusion regimens, most clinicians and investigators describe the flow in the infarct vessel according to the TIMI (Thrombolysis In Myocardial Infarction) trial grading system (Fig. 52-4).⁴⁹ Importantly, an angiographic snapshot in time does not reflect the fluctuating status of flow in the infarct vessel, which may undergo repeated cycles of patency and reocclusion before or during fibrinolysis.

When assessed 60 to 90 minutes after the start of fibrinolytic therapy,^{2,48} the finding of TIMI grade 3 flow is far superior to grade 2 in terms of reduction of infarct size and both short-term and long-term mortality benefit. Therefore TIMI grade 3 flow should be the goal when assessing flow in the epicardial infarct artery (Fig. 52-4).

The TIMI Frame Count. In an effort to provide a more quantitative statement of the briskness of coronary blood flow in the infarct artery and to account for differences in the size and length of vessels (e.g., left anterior descending versus right coronary artery) and interobserver variability, Gibson and coworkers developed the TIMI frame count—a simple count of the number of angiographic frames elapsed until the contrast material arrives in the distal bed of the vessel of interest. This objective and quantitative index of coronary blood flow independently predicts in-hospital mortality from STEMI and also discriminates patients with TIMI grade 3 flow into low-risk and high-risk groups. The TIMI frame count can also be used to quantitate coronary blood flow (mL/sec), as calculated by

$$21 \div (\text{Observed TIMI frame count}) \times 1.7$$

(based on Doppler velocity wire data showing that normal flow equals 1.7 cm³/sec, which is proportional to 21 frames). The calculated coronary perfusion is related to mortality in patients treated with fibrinolytics or primary PCI and serves to assess various modalities for reperfusion in patients with STEMI.

Myocardial Perfusion. Despite the priority placed on normalization of flow in the epicardial infarct-related artery, reperfusion in patients with STEMI is ultimately intended to improve actual myocardial perfusion in the infarct zone. Myocardial perfusion cannot be improved adequately without restoration of flow in the occluded infarct-related artery, but even patients with TIMI grade 3 flow may not achieve adequate myocardial perfusion, especially if the delay between the onset of symptoms and restoration of epicardial flow is long.^{50,51} The term myocardial “no-reflow” has been used to describe a state with reduced myocardial perfusion after opening of

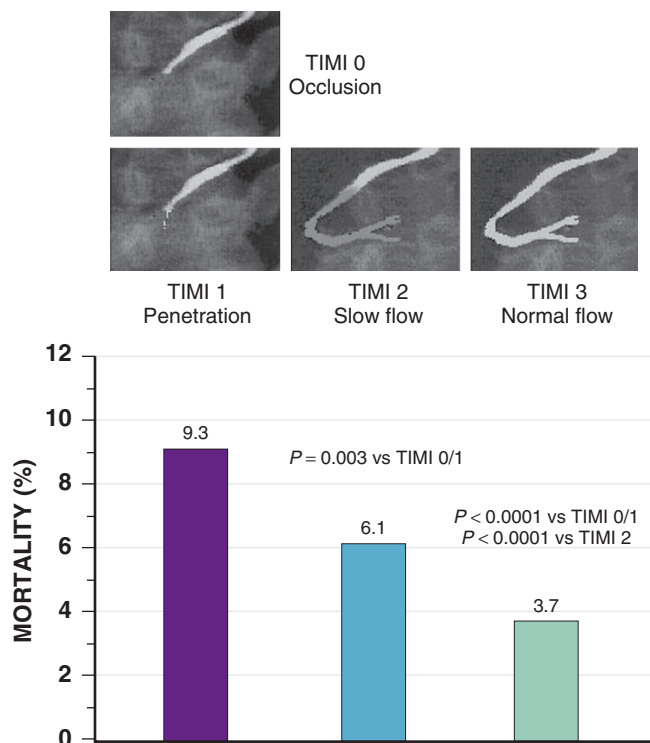

FIGURE 52-4 Correlation of TIMI flow grade and mortality. A pooled analysis of data from 5498 patients in several angiographic trials of reperfusion for STEMI showed a gradient of mortality when the angiographic findings were stratified by TIMI flow grade. Patients with TIMI 0 or TIMI 1 flow had the highest rate of mortality, TIMI 2 flow associated with an intermediate rate of mortality, and the lowest rate of mortality was observed in patients with TIMI 3 flow. (Courtesy Dr. Michael Gibson, personal communication.)

an epicardial infarct-related artery.⁵² The two major impediments to normalization of myocardial perfusion are microvascular damage (Fig. 52-5)⁵⁰ and reperfusion injury. Obstruction of the distal microvasculature in the downstream bed of the infarct-related artery results from platelet microemboli and thrombi. Fibrinolysis may actually exacerbate microembolization of platelet aggregates because of the exposure of clot-bound thrombin, an extremely potent platelet agonist. Spasm can also occur in the microvasculature as a consequence of release of substances from activated platelets. Reperfusion injury results in cellular edema, formation of reactive oxygen species, and calcium overload. In addition, cytokine activation leads to the accumulation of neutrophils and inflammatory mediators that contribute to tissue injury.⁵²

Several techniques can be used to evaluate the adequacy of myocardial perfusion.

Electrocardiography. Electrocardiographic ST-segment resolution strongly predicts outcome in patients with STEMI but is a better predictor of an occluded artery than a patent infarct-related artery.^{53,54} The persistence of ST-segment elevation after angiographically successful primary PCI identifies patients with a higher risk for left ventricular dysfunction and mortality, presumably because of microvascular damage in the infarct zone. Thus the 12-lead ECG is a marker of the biologic integrity of myocytes in the infarct zone and can reflect inadequate myocardial perfusion even in the presence of TIMI grade 3 flow.⁵⁵ The extent of ST-segment resolution provides powerful prognostic information early in the management of patients with STEMI.⁵⁶ Given the dynamic nature of coronary occlusion, continuous ST-segment monitoring may prove more informative than static 12-lead electrocardiographic recordings.

Noninvasive Imaging. Defects in perfusion patterns seen with myocardial contrast-enhanced echocardiography correlate with regional wall motion abnormalities and lack of myocardial viability on dobutamine stress echocardiography (see Chapter 14).⁵⁷ Contrast-enhanced cardiac magnetic resonance imaging (MRI) can also identify regions of microvascular obstruction, which are associated with an adverse long-term prognosis (see Chapter 17).⁵⁸

FIGURE 52-5 Points of possible failure of reperfusion therapy. Complete reperfusion requires successful restoration of normal flow in both the epicardial coronary artery and the distal coronary microvasculature, termed myocardial tissue-level reperfusion. Failure of epicardial reperfusion can result from failure to induce a lytic state or from persistent mechanical obstruction at the site of occlusion. Failure of microvascular reperfusion is caused by a combination of platelet microthrombi followed by endothelial swelling and myocardial edema ("no reflow"). Reperfusion may fail because of persistent occlusion of the epicardial infarct-related artery (TIMI grades 0 and 1), patency of an epicardial artery in the presence of impaired (TIMI grade 2) flow, or microvascular occlusion in the presence of angiographically normal (TIMI grade 3) flow. Successful reperfusion requires a patent artery with an intact microvascular network. (Modified from Davies CH, Ormerod OJ: Failed coronary thrombolysis. *Lancet* 351:1191, 1998.)

Invasive Assessment. Doppler flow wire studies can also define abnormalities in myocardial perfusion. In addition, an angiographic method for assessing myocardial perfusion has been developed by Gibson and colleagues: the TIMI myocardial perfusion (TMP) grade (Fig. 52-6).^{50,59} Abnormalities associated with increasing myocardial perfusion, as assessed by the TIMI grade, correlate with unfavorable ventricular remodeling and risk for mortality even after adjusting for the presence of TIMI grade 3 flow or a normal TIMI frame count.^{50,60}

Effect of Fibrinolytic Therapy on Mortality

Early intravenous fibrinolysis improves survival in patients with STEMI.¹ The benefit of fibrinolytic therapy appears to be greatest when agents are administered as early as possible, with the most dramatic results occurring when the drug is given less than 1 to 2 hours after symptoms begin.²

The Fibrinolytic Therapy Trialists' (FTT) Collaborative Group performed a comprehensive overview of nine trials of thrombolytic therapy, each of which enrolled more than 1000 patients. Absolute mortality rates for the control and fibrinolytic groups stratified by initial features are shown in Figure 52-7. The overall results indicated an 18% reduction in short-term mortality, but as much as a 25% reduction in mortality in the subset of 45,000 patients with ST-segment elevation or bundle branch block. Two trials, LATE (Late Assessment of Thrombolytic Efficacy) and EMERAS (Estudio Multicéntrico Estreptoquinasa Repúblicas de América del Sur), when viewed together, provide evidence that a reduction in mortality may still be observed in patients treated with thrombolytic agents between 6 and 12 hours after the onset of ischemic symptoms. Data from the LATE and EMERAS trials and the FTT overview form the basis for extending the window of treatment with fibrinolytics up to 12 hours after the onset of symptoms. As cited in the American College of Cardiology Foundation (ACCF)/AHA guidelines for the management of ST-elevation MI (referred to hereafter as the guidelines), Boersma and colleagues pooled the trials in the FTT overview, two smaller studies with data on time until randomization, and 11 additional trials.¹ Patients were divided into six time categories from the onset of symptoms to randomization. A nonlinear relationship of treatment benefit to time was observed, with the greatest benefit occurring in the first 1 to 2 hours after the onset of symptoms.¹

Comparison of Fibrinolytic Agents (See Chapter 82)

Comparative features of the approved fibrinolytic agents for intravenous therapy are presented in [Table 52-5](#). All fibrinolytic agents exert their effect by converting the proenzyme plasminogen to the active enzyme plasmin. The so-called fibrin-specific fibrinolytics are those that are relatively inactive in the absence of fibrin but in its presence substantially increase their activity on plasminogen.

The tissue plasminogen activator (t-PA) molecule contains five domains ([Fig. 52-9](#)).⁶⁴ In the absence of fibrin, t-PA is a weak plasminogen activator; fibrin provides a scaffold on which t-PA and plasminogen are held in such a way that the catalytic efficiency of plasminogen activating t-PA is increased many-fold. A dose regimen of t-PA administered over a 90-minute period produces more rapid thrombolysis than does a 3-hour fixed-rate infusion. Therefore the recommended dosage for t-PA is the 90-minute “accelerated” regimen.

Modifications in the native t-PA structure have yielded a group of fibrinolytic agents with prolonged plasma clearance that allows them to be administered as a bolus ([Fig. 52-9](#) and [Table 52-5](#)) rather than as the bolus and infusion by which accelerated-dose t-PA is administered.⁶⁴ Reteplase (double fixed-dose

bolus) and tenecteplase (single weight-based bolus) have both been compared with accelerated t-PA. Both these newer agents were associated with mortality rates similar to that achieved with accelerated t-PA, but with more convenient dosing. In one large trial, tenecteplase was found to have a lower rate of major bleeding than accelerated t-PA did.

Other Fibrinolytic Agents

Streptokinase, a protein secreted by several species of streptococci, binds and activates human plasminogen and is an inexpensive and effective fibrinolytic agent that is still used in some regions of the world. Urokinase is used for STEMI on rare occasions as an intracoronary infusion.

Effect on Left Ventricular Function

As with survival, improvement in global left ventricular function is related to the time of initiation of fibrinolytic treatment, with the greatest improvement occurring with the earliest therapy.² Although precise measurements of infarct size would be an ideal endpoint for clinical reperfusion studies, such measures have proved impractical. Attempts to use the left ventricular ejection fraction as a surrogate for infarct size have not been productive because little difference is seen in the ejection fraction between treatment groups that show a significant difference in mortality. Methods of assessing left ventricular function, such as end-systolic volume or quantitative echocardiography, are more revealing because patients with smaller volumes and better-preserved ventricular shape have improved survival. The myocardial salvage index, defined as the difference between the initial perfusion defect (e.g., by sestamibi scintigraphy) and the final perfusion defect, is a useful means for comparing the effectiveness of reperfusion therapies.⁶⁵ Characterization of left ventricular volumes concurrently with the extent of scar as revealed by myocardial

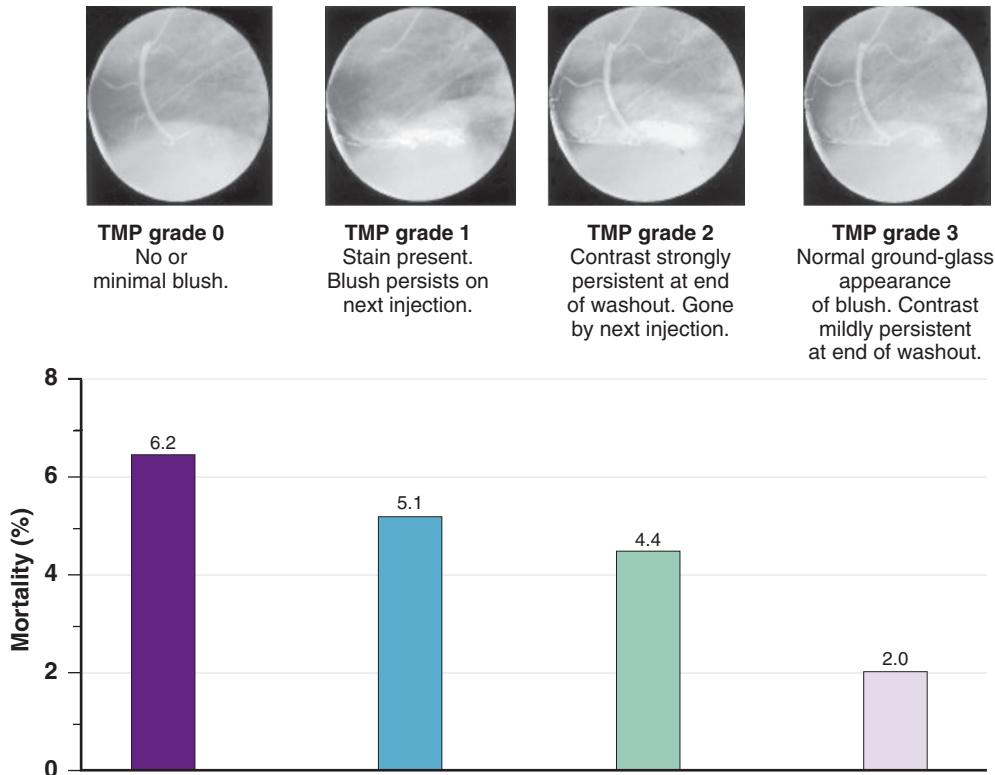

FIGURE 52-6 Relationship between angiographic assessment of myocardial tissue-level reperfusion categorized by TIMI myocardial perfusion (TMP) grade and mortality. TMP grade 0 or no perfusion of the myocardium is associated with the highest rate of mortality. If a stain of the myocardium is present (grade 1), mortality is also high. A reduction in mortality is seen if the dye enters the microvasculature but is still persistent at the end of the washout phase (grade 2). The lowest mortality rate is observed in patients with normal perfusion (grade 3), with the dye being minimally persistent at the end of the washout phase. (From Gibson CM, Cannon CP, Murphy SA, et al: Relationship of TIMI myocardial perfusion grade to mortality after administration of thrombolytic drugs. *Circulation* 101:125, 2000.)

The mortality effect of fibrinolytic therapy in elderly patients is of considerable interest and controversy. Although patients older than 75 years were initially excluded from randomized trials of fibrinolytic therapy, they now constitute approximately 15% of those studied in trials of fibrinolysis and approximately 35% of those analyzed in registries of patients with STEMI.⁶¹ Barriers to initiation of therapy in older patients with STEMI include a protracted period of delay in seeking medical care, a lower incidence of ischemic discomfort and greater incidence of atypical symptoms and concomitant illnesses, and an increased incidence of nondiagnostic findings on the ECG.⁶¹ Younger patients with STEMI achieve a slightly greater relative reduction in mortality than elderly patients do, but the higher absolute mortality in elderly patients results in similar absolute reductions in mortality.⁶²

Several models have integrated the many clinical variables that affect a patient's risk for mortality before the administration of fibrinolytic therapy. A convenient, simple, bedside risk-scoring system for predicting 30-day mortality at initial evaluation of fibrinolytic-eligible patients with STEMI was developed by Morrow by using the InTIME-II trial database ([Fig. 52-8](#)).⁶³ Modeling of mortality risk cannot cover all clinical scenarios, however, and should supplement clinical judgment in individual cases. For example, patients with inferior STEMI who might otherwise be considered to have a low risk for mortality and for whom many physicians have questioned the benefits of fibrinolytic therapy might be in a higher mortality risk subgroup if their inferior infarction is associated with right ventricular infarction, precordial ST-segment depression, or ST-segment elevation in the lateral precordial leads.

The short-term survival benefit enjoyed by patients who receive fibrinolytic therapy is maintained over the 1- to 10-year follow-up. Room for improvement remains. Advances in adjunctive antiplatelet and antithrombin therapies have led to reductions in the rate of reinfarction after fibrinolysis for STEMI.^{2,48}

FIGURE 52-7 Differences in mortality during days 0 to 35, subdivided by initial features, in a collaborative overview of results from nine trials of thrombolytic therapy. Absolute mortality rates are shown for the fibrinolytic and control groups in the **center** of the figure for each of the clinical features at initial encounter, listed on the **left side** of the figure. The ratio of the odds of death in the fibrinolytic group to that in the control group is shown for each subdivision (colored squares), along with its 99% CI (horizontal line). The summary OR at the **bottom** of the figure corresponds to an 18% proportional reduction in 35-day mortality and is highly statistically significant. This translates to a reduction of 18 deaths per 1000 patients treated with thrombolytic agents. BBB, bundle branch block; BP, blood pressure; SD, standard deviation. (From Fibrinolytic Therapy Trialists' [FTT] Collaborative Group: Indications for fibrinolytic therapy in suspected acute myocardial infarction: Collaborative overview of mortality and major morbidity results from all randomized trials of more than 1000 patients. *Lancet* 343:311, 1994.)

FIGURE 52-8 TIMI risk score for STEMI predicting 30-day mortality. h/o, history of; HTN, hypertension; LBBB, left bundle branch block. (From Morrow DA, Antman EM, Charlesworth A, et al: The TIMI risk score for ST elevation myocardial infarction: A convenient, bedside, clinical score for risk assessment at presentation: An In TIME II substudy. *Circulation* 102:2031, 2000.)

TABLE 52-5 Comparison of Approved Fibrinolytic Agents

FIBRINOLYTIC AGENT	DOSE	FIBRIN SPECIFICITY	FIBRINOGEN DEPLETION	ANTIGENIC	PATENCY RATE (90-MIN TIMI 2 OR 3 FLOW)
Fibrin Specific					
Tenecteplase (TNK)	Single IV weight-based bolus [†]	++++	Minimal	No	85%
Retepase (r-PA)	10 units + 10-unit IV boluses given 30 min apart	++	Moderate	No	84%
Alteplase (t-PA)	90-min weight-based infusion [‡]	++	Mild	No	73-84%
Non-Fibrin Specific					
Streptokinase [§]	1.5 million units IV given over 30-60 min	No	Marked	Yes [¶]	60-68%

*Strength of fibrin specificity: ++++ is stronger; ++ is less strong.

[†]Bolus of 30 mg for weight less than 60 kg, 35 mg for 60 to 69 kg, 40 mg for 70 to 79 kg, 45 mg for 80 to 89 kg, and 50 mg for 90 kg or greater.

[‡]Bolus of 15 mg, infusion of 0.75 mg/kg for 30 minutes (maximum, 50 mg), then 0.5 mg/kg (maximum, 35 mg) over the next 60 minutes; the total dose not to exceed 100 mg.

[§]Streptokinase is no longer marketed in the United States but is available in other countries.

[¶]Streptokinase is highly antigenic and absolutely contraindicated within 6 months of previous exposure because of the potential for serious allergic reaction.

r-PA = reteplase plasminogen activator; t-PA = tissue plasminogen activator.

From O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 61:e78, 2013.

FIGURE 52-9 Molecular structure of alteplase (t-PA), reteplase (r-PA), and tenecteplase (TNK). Streptokinase (SK) is the least fibrin-specific thrombolytic agent in clinical use; the progressive increase in relative fibrin specificity for the various thrombolytics is shown at the bottom. (Modified from Brener SJ, Topol EJ: Third-generation thrombolytic agents for acute myocardial infarction. In Topol EJ [ed]: *Acute Coronary Syndromes*. New York, Marcel Dekker, 1998, p 169.)

delayed enhancement, as well as ischemia with adenosine stress perfusion and cardiac MRI, provides significant incremental prognostic information over other clinical variables and is an emerging strategy for risk stratification after STEMI.⁶⁶⁻⁶⁸

Complications of Fibrinolytic Therapy

Bleeding complications are most common, and intracranial hemorrhage is the most serious complication of fibrinolytic therapy; its frequency is generally less than 1% but varies with the clinical

FIGURE 52-10 Estimation of risk for intracranial hemorrhage (ICH) with fibrinolysis. The number of risk factors is the sum of the points based on criteria established in the studies shown. Although the exact risk factors varied among the studies, common risk factors across each of the studies include increased age, low body weight, and hypertension on admission. See references for further discussion. (Data from Brass LM, Lichtman JH, Wang Y, et al: Intracranial hemorrhage associated with thrombolytic therapy for elderly patients with acute myocardial infarction: Results from the Cooperative Cardiovascular Project. *Stroke* 31:1802, 2000.)

characteristics of the patient and the fibrinolytic agent used (Fig. 52-10).¹ Intracranial bleeding in the setting of fibrinolysis for STEMI is associated with a high case fatality rate. Nonintracranial bleeding can also result in increased morbidity, but whether it is causal of higher overall mortality, after taking into account the higher-risk clinical characteristics that also predispose patients to bleeding during treatment of STEMI, is uncertain.^{69,70}

Reports have demonstrated an “early hazard” with fibrinolytic therapy—that is, an excess of deaths in the first 24 hours in fibrinolytic-treated patients when compared with control subjects (especially in elderly patients treated more than 12 hours after symptom onset). However, this excess early mortality is more than offset by deaths prevented beyond the first day, with an average 18% (range, 13% to 23%) reduction in mortality by 35 days as compared with offering no reperfusion therapy.¹ The mechanisms responsible for this early hazard are not clear but are probably multiple, including an increased risk for myocardial rupture, fatal intracranial hemorrhage, and possible myocardial reperfusion injury.

Recent exposure to streptococci or streptokinase produces some degree of antibody-mediated resistance to streptokinase (and anistreplase) in most patients. Although such resistance is only rarely

of clinical consequence, patients should not receive streptokinase for STEMI if they have been treated with a streptokinase product within the past 6 months.

Recommendations for Fibrinolytic Therapy

As described in the preceding sections, the benefits of fibrinolytic therapy in patients with STEMI are well established, with a time-dependent improvement in survival rates during the initial 12 hours after the onset of symptoms. When a patient arrives at a PCI-capable facility, primary PCI is the preferred mode of reperfusion therapy (see the section [Selection of Reperfusion Strategy](#)).^{1,4} However, many health care facilities do not have ready access to timely PCI; if the delay from first medical contact to performing primary PCI is anticipated to exceed 120 minutes, administration of a fibrinolytic is indicated for the treatment of STEMI within 12 hours of onset in the absence of contraindications.¹ In addition, even when interhospital transport times are expected to be short, there may be advantages to immediate initiation of fibrinolytic therapy versus incurring any delay until primary PCI in patients with STEMI and low bleeding risk who are initially seen very early in the course.¹

Choice of Agent

The choice of fibrinolytic in hospital systems is generally driven by the desire to establish consistent protocols within the health care system by weighing ease of dosing, cost, and other institutional preferences. In patients seen early with acceptable bleeding risk, a high-intensity fibrin-specific regimen, such as accelerated t-PA, reteplase, or tenecteplase, is usually preferable.¹ In patients whose risk for death is low (e.g., a young patient with a small inferior MI) and whose risk for intracranial hemorrhage is increased (e.g., acute hypertension), administration of streptokinase is reasonable, but rarely done in the United States. In patients who are to be treated with a fibrinolytic and in whom t-PA would have been selected as the agent of choice in the past, we believe that clinicians should now consider using a bolus fibrinolytic such as reteplase or tenecteplase. The rationale for this recommendation is that bolus fibrinolytics are easy to administer, have a lower chance of medication errors (and the associated increase in mortality when such errors occur), and are associated with less noncerebral bleeding—as well as offering the potential for prehospital treatment.⁶⁴

Late Therapy

No mortality benefit was demonstrated in the LATE and EMERAS trials when fibrinolytics were routinely administered to patients between 12 and 24 hours, although we believe that it is still reasonable to consider fibrinolytic therapy when PCI is not available for appropriately selected patients with clinical and/or electrocardiographic evidence of ongoing ischemia within 12 to 24 hours of symptom onset and a large area of myocardium at risk or hemodynamic instability. Persistent chest pain late after the onset of symptoms correlates with a higher incidence of collateral or anterograde flow in the infarct zone and is therefore a marker for viable myocardium that might be salvaged. Because elderly patients treated with fibrinolytic agents more than 12 hours after the onset of symptoms have an increased risk for cardiac rupture, we believe that restricting late administration of a fibrinolytic to patients younger than 65 years with ongoing ischemia, especially those with large anterior infarctions, is preferable. An elderly patient with ongoing ischemic symptoms but initially seen late (>12 hours) is probably better managed with PCI than with fibrinolytic therapy.

General Considerations

Before fibrinolytic therapy is instituted, consideration should be given to the patient's need for intravascular catheterization, as would be required for placement of an arterial pressure monitoring line, a pulmonary artery catheter for hemodynamic monitoring, or a temporary transvenous pacemaker. If any of these are required, ideally they should be placed as expeditiously as possible *before* infusion of the fibrinolytic agent. If such procedures require an additional delay of more than 30 minutes, they should be deferred for as long as possible

after fibrinolytic therapy is begun. In the early hours after institution of fibrinolytic therapy, such catheterization should be performed only if crucial to the patient's survival, and then sites at which excessive bleeding can be controlled should be chosen (e.g., subclavian vein catheterization should be avoided).

Administration of anticoagulant and antiplatelet agents as an adjunct to thrombolysis is discussed in detail in a subsequent section (see [Anticoagulant and Antiplatelet Therapy](#)).

Intracoronary Fibrinolysis

In contemporary practice, patients are more likely to be treated with PCI. This evolution has revived the concept of delivering fibrinolytic agents via the intracoronary route, but current efforts are largely restricted to adjunctive use during complicated PCI procedures.⁷¹

Catheter-Based Reperfusion Strategies (See also [Chapter 55](#))

Reperfusion of the infarct artery can also be achieved via a catheter-based strategy. This approach has evolved from passage of a balloon catheter over a guidewire to now include potent oral antiplatelet therapy, multiple options for anticoagulants, coronary stents, and thrombectomy.¹ When PCI is used as primary reperfusion therapy in patients with STEMI, it is referred to as direct or primary PCI (see [Fig. 52-1](#)). After fibrinolysis has failed to reperfuse the infarct vessel or a severe stenosis is present in the infarct vessel, rescue PCI can be performed ([Fig. 52-1](#)). A strategy of routine delayed angiography and PCI after successful fibrinolytic therapy may also be considered ([Fig. 52-1](#)).^{72,73} Finally, a conservative approach of elective PCI only when spontaneous or exercise-provoked ischemia occurs may be used to manage patients with STEMI, regardless of whether they have received a previous course of fibrinolytic therapy or no initial reperfusion therapy ([Fig. 52-1](#)).¹ Primary PCI and the management of significant stenoses in nonculprit coronary arteries are discussed in [Chapter 55](#). This chapter discusses decision making regarding the selection of initial reperfusion therapy and decisions on referral for PCI in patients who have undergone initial fibrinolysis (see also [Chapter 55](#)).

Surgical Reperfusion

Despite the extensive improvement in intraoperative preservation with cardioplegia and hypothermia and numerous surgical techniques, providing surgical reperfusion in timely fashion is not logistically possible. Therefore patients with STEMI who are candidates for reperfusion should undergo either fibrinolysis or PCI. However, patients with STEMI are currently referred for coronary artery bypass grafting (CABG) for one of the following indications: persistent or recurrent ischemia despite fibrinolysis or primary PCI with residual coronary disease not amenable to PCI, high-risk coronary anatomy (e.g., left main stenosis) discovered at initial catheterization, or a complication of STEMI such as ventricular septal rupture or severe mitral regurgitation caused by papillary muscle dysfunction. STEMI patients with continued severe ischemic and hemodynamic instability will probably benefit from emergency revascularization.

Patients who successfully undergo fibrinolysis but have important residual stenoses and on anatomic grounds are more suitable for surgical revascularization than for PCI have undergone CABG with quite low rates of mortality ($\approx 4\%$) and morbidity, provided that the procedure is carried out more than 24 hours after STEMI; patients requiring urgent or emergency CABG within 24 to 48 hours of STEMI have mortality rates between 12% and 15%.¹ When surgery is performed under urgent conditions with active and ongoing ischemia or cardiogenic shock, operative mortality rates are higher, in large part reflecting the patient's overall condition that necessitated emergency surgery.

Selection of Reperfusion Strategy

When performed rapidly after arrival at an experienced center, primary PCI is superior to pharmacologic reperfusion therapy.^{1,74,75}

FIGURE 52-11 Relative treatment effect associated with several acute reperfusion modalities in patients with STEMI. Data are ORs and 95% CIs. Ctrl = control; EXP = experimental. (Modified from Boersma E, Mercado N, Poldermans, et al: Acute myocardial infarction. *Lancet* 361:851, 2003.)

Nevertheless, decision making for individual patients remains complex regarding the optimum form of reperfusion therapy when a delay until PCI can be performed is anticipated, such as in centers without 24-hour availability of primary PCI.¹ This controversy has been difficult to resolve in the context of a dynamic evidence base and the absence of adequately powered definitive trials of reperfusion in patients with STEMI when immediate primary PCI is not an option. Moreover, newer fibrinolytic agents and combinations of adjunctive treatments have improved medical measures to restore and maintain flow in the infarct artery (Fig. 52-11). At the same time, improvements in catheterization laboratory facilities, new stents, evolution of adjunctive antithrombotic therapy, thrombus aspiration devices, and the development of collaborative systems for rapid transfer for invasive therapy have improved the efficacy and safety of primary PCI in patients with STEMI, including those being transferred for primary PCI (see Chapter 55).⁷⁶ High-volume operators and centers can consistently achieve better outcomes in patients with STEMI.⁷⁷ Selection of the optimal form of reperfusion therapy therefore involves judgments regarding both system resources and individual patient characteristics.

For patients who arrive at an experienced primary PCI center, primary PCI should be performed in those with STEMI who are seen within 12 hours of symptom onset and those with later arrival who have ongoing ischemia or shock. In patients taken to centers that are not PCI capable, the following issues should be considered in choosing the approach to reperfusion (see Fig. 52-1 and Table 52-4):

1. **Time from onset of symptoms to initiation of reperfusion therapy:** PCI is preferable in patients with late arrival, particularly those initially seen more than 12 hours after symptom onset.
2. **Risk for death after STEMI:** The mortality benefit associated with PCI is largest in patients at highest risk for mortality; the mortality benefit of PCI decreases progressively as the patient's risk for death from STEMI decreases such that the mortality advantage of

PCI is no longer evident in patients whose 30-day mortality rate is estimated to be between 2% and 3% if treated with fibrinolytic therapy.

3. **Presence of shock:** Patients in cardiogenic shock have improved survival if they are treated with an early revascularization strategy (PCI and/or CABG as indicated).
4. **Risk for bleeding:** In patients with an increased risk for bleeding, particularly intracranial hemorrhage, therapeutic decision making strongly favors a PCI-based reperfusion strategy (see Fig. 52-10). If PCI is unavailable, the benefit of pharmacologic reperfusion should be balanced against the risk for bleeding. A decision analysis suggests that when PCI is not available, fibrinolytic therapy should still be favored over no reperfusion treatment until the risk for life-threatening bleeding exceeds 4%.
5. **Time required for transportation to a skilled PCI center:** The greatest operational impediment to routine implementation of a PCI reperfusion strategy is the delay required for transportation to a skilled PCI center (Fig. 52-12; also see Fig. 52-1 and Table 52-1).⁷⁸ Trials conducted in health care systems with extremely short transportation and door-to-balloon times at PCI centers have demonstrated that referral to a PCI center can be superior to fibrinolysis administered at a local hospital.^{78,79} If the delay to implementation of primary PCI is substantial, however, the mortality advantage over administration of a fibrin-specific agent is lost. The best estimate of the time delay at which this advantage is lost is 1 to 2 hours, but it may vary depending on the timing of initial evaluation and the extent of myocardium at risk.⁷⁸

Based on the aforementioned considerations, clinicians should make an integrated assessment of the time since the onset of symptoms (see Figs. 52-1, 52-2, and 52-3), risk for death after STEMI (see Fig. 52-8), risk for bleeding if a fibrinolytic is administered (see Fig. 52-10), and time required for transportation to a skilled PCI center (see Fig. 52-1 and 52-3). Reducing this decision making to a

“one-size-fits-all” approach is not possible. Primary PCI is generally preferred, except when a patient with low bleeding risk arrives very early after the onset of symptoms (1 to 2 hours) at a non-PCI-capable hospital and the delay in transfer for primary PCI is anticipated to be long (Fig. 52-12). When fibrinolysis is performed early, particularly in the prehospital setting, and is followed by coronary angiography and PCI when appropriate, the 1-year survival rate is comparable to that achieved with primary PCI.⁸⁰ Importantly, when the diagnosis of STEMI is in doubt, an invasive strategy is clearly the preferred strategy because it not only provides key diagnostic information regarding the patient’s symptoms but does so without the risk for intracranial hemorrhage associated with fibrinolysis.

Referral for Angiography with the Intent of Revascularization after Initial Fibrinolysis

Patients with STEMI who are initially managed by fibrinolysis at a non-PCI-capable center may be appropriate for transfer for coronary angiography because of the development of cardiogenic shock or severe heart failure, for failed reperfusion with a fibrinolytic, or as part of an invasive strategy in stable patients with the intention of performing PCI 3 to 24 hours after fibrinolysis (Table 52-6; also see Fig. 52-1). Performance of PCI in patients with STEMI and shock has been discussed.

Studies of patients undergoing angiography and PCI after suspected failure of reperfusion with fibrinolysis have demonstrated a trend toward a lower mortality rate and significantly lower rates of recurrent MI and heart failure in those treated with rescue PCI versus continued medical therapy, including readministration of a fibrinolytic agent. In the REACT (Rapid Early Action for Coronary Treatment) study, patients with suspected failed reperfusion at 90 minutes by electrocardiographic criteria were randomly assigned to one of three treatment arms: rescue PCI, conservative care, or repeated fibrinolytic therapy. The composite of death, reinfarction, stroke, or severe heart failure at 6 months was significantly lower in patients randomly assigned to rescue PCI than in the two other treatment groups.¹ More minor bleeding, however, occurred in patients randomly assigned to rescue PCI.

The option of administration of a fibrinolytic agent at non-PCI-capable hospitals, followed by routine transfer for angiography and PCI if indicated, has been advanced as an attractive strategy to offer timely reperfusion therapy and arrange a “nonemergency” transfer

for subsequent procedures to reduce the risk for subsequent reinfarction. This approach is supported indirectly by retrospective analyses of trials of fibrinolytic therapy that suggest a lower risk for recurrent MI and a lower 2-year mortality rate in patients who subsequently undergo early PCI. The limited randomized trials evaluating a strategy of routine catheterization after fibrinolysis have provided mixed results. Nevertheless, overall, these trials have suggested improvement in clinical outcomes in patients transferred for early catheterization, particularly those at higher risk for death and recurrent ischemia (Fig. 52-13).¹ In the largest of these studies, TRANSFER-AMI (Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction; N = 1059), immediate transfer for angiography versus conservative care reduced the composite endpoint of death, recurrent MI, recurrent ischemia, new or worsening heart failure, or shock at 30 days.⁷³ In a meta-analysis that included seven randomized trials of early transfer for catheterization, a strategy of routine early catheterization after fibrinolysis was associated with a statistically significant reduction in the incidence of death or MI at 30 days and at 1 year without an increase in the risk for major bleeding.⁸¹ Notably, the clinical trials that assessed routine invasive evaluation after initial fibrinolysis used a time window of 0 to 24 hours for the “early invasive” strategy, thus supporting earlier transfer after administration of fibrinolytic therapy, even for patients without high-risk features. Although we believe that there will probably be continued benefit even beyond 24 hours in patients with a patent but stenotic infarct artery after initial successful reperfusion, later time windows have not been directly examined. Because of the associated increased bleeding risk, very early (<2 to 3 hours) catheterization after the administration of fibrinolytic therapy with the intent to perform revascularization should be reserved for patients with evidence of failed fibrinolysis and significant myocardial jeopardy, for whom rescue PCI would be appropriate. In addition, when STEMI is suspected to have occurred by a mechanism other than thrombotic occlusion at the site of atherosclerotic plaque, coronary angiography may provide diagnostic information and direct specific therapy.

In summary, delayed coronary angiography with PCI of the infarct artery is indicated in patients initially treated with a noninvasive strategy (i.e., with fibrinolysis or without reperfusion therapy) who become unstable after cardiogenic shock, acute severe heart failure, or unstable postinfarction angina develops, provided that invasive management is not considered futile or inappropriate (Table 52-6).

Delayed PCI also appears to be reasonable in patients with failed fibrinolysis or reocclusion of the infarct artery or in those who demonstrate significant residual ischemia during hospitalization after initial noninvasive management. The benefits of routine (non-ischemia-driven) PCI on an angiographically significant stenosis in a patent infarct artery more than 24 hours after STEMI are less well established, and delayed PCI on a totally occluded infarct artery longer than 24 hours after STEMI should not be undertaken in clinically stable patients without evidence of severe ischemia.¹

Patients Not Eligible for Reperfusion Therapy

Aspirin and antithrombin therapy can be prescribed for patients who are not candidates for acute reperfusion because of lack of availability of PCI and contraindications to fibrinolysis. In the setting of absolute contraindications to fibrinolysis (see Table 52-4) and lack of access to PCI facilities, antithrombotic therapy should be initiated because of the small but finite chance

FIGURE 52-12 Relationship between PCI-related delay (minutes) during transfer from a non-PCI-capable hospital to a PCI-capable hospital and in-hospital mortality. The dotted line represents 95% CIs. XDB-DN indicates transfer delay (transfer door-to-balloon minus door-to-needle time). With delays longer than 120 minutes between administration of a fibrinolytic on-site and balloon (or device) time at a receiving hospital, the on-site fibrinolytic strategy becomes preferable with respect to mortality risk when compared with transfer for PCI. O-FT = On-site fibrinolytic therapy. X-PCI = transfer PCI. (From Pinto DS, Frederick PD, Anjan K, et al: Benefit of transferring ST-segment-elevation myocardial infarction patients for percutaneous coronary intervention compared with administration of onsite fibrinolytic as delays increase. *Circulation* 124:2518, 2011.)

TABLE 52-6 Indications for Coronary Angiography in Patients Who Were Managed with Fibrinolytic Therapy or Who Did Not Receive Reperfusion Therapy

RECOMMENDATION	COR	LOE
Cardiogenic shock or acute severe HF that develops after initial evaluation	I	B
Intermediate- or high-risk findings on predischARGE noninvasive ischemia testing	I	B
Spontaneous or easily provoked myocardial ischemia	I	C
Failed reperfusion or reocclusion after fibrinolytic therapy	IIa	B
Stable* patients after successful fibrinolysis—before discharge and ideally between 3 and 24 hr	IIa	B

*Although individual circumstances vary, clinical stability is defined as the absence of low output, hypotension, persistent tachycardia, apparent shock, high-grade ventricular or symptomatic supraventricular tachyarrhythmias, and spontaneous recurrent ischemia.

COR = class of recommendation; HF = heart failure; LOE = level of evidence.

(≈10%) of restoring TIMI grade 3 flow in the infarct vessel and decreasing the chance of thrombotic complications of STEMI.

Anticoagulant and Antiplatelet Therapy

Anticoagulant Therapy

The rationale for administering anticoagulant therapy acutely to patients with STEMI includes establishing and maintaining patency of the infarct-related artery, regardless of whether a patient receives fibrinolytic therapy (Fig. 52-14), and preventing deep venous thrombosis, pulmonary embolism, ventricular thrombus formation, and cerebral embolization.

Effect of Heparin on Mortality

Randomized trials of patients with STEMI conducted in the prefibrinolytic era showed a lower risk for reinfarction, pulmonary embolism, and stroke in those who received intravenous heparin, thus supporting the administration of heparin to STEMI patients not treated with fibrinolytic therapy. With the introduction of the fibrinolytic era and, importantly, after publication of the ISIS-2 (Second International Study of Infarct Survival) trial, the situation became more complicated because of strong evidence of a

FIGURE 52-13 Primary outcome of trials of routine versus ischemia-driven (or delayed) catheterization and PCI after fibrinolytic therapy. Trials comparing routine early catheterization after fibrinolytic therapy with either an ischemia-driven approach or routine delayed catheterization generally showed a consistent pattern of benefit with a strategy of routine transfer for invasive evaluation. The darker bars represent patients who underwent routine early catheterization after fibrinolytic therapy. The lighter bars represent patients who underwent either an ischemia-guided or routine delayed catheterization approach. arrhy = arrhythmia; CAPITAL-AMI = Combined Angioplasty and Pharmacological Intervention Versus Thrombolysis Alone in Acute Myocardial Infarction; CARESS-in-AMI = Combined Abciximab Reteplase Stent Study in Acute Myocardial Infarction; CHF = congestive heart failure; D = death; GRACIA = Grupo de Análisis de la Cardiopatía Isquémica Aguda; NORDISTEMI = Norwegian study on District treatment of ST-Elevation Myocardial Infarction; revasc = ischemia-driven revascularization; RI = recurrent ischemia; SIAM-3 = Southwest German Interventional Study in Acute Myocardial Infarction; TLR = target lesion revascularization; TRANSFER-AMI = Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction; WEST = Which Early ST-Elevated Myocardial Infarction Therapy. (Modified from O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e383, 2013.)

FIGURE 52-14 Targets for therapy during reperfusion of patients with STEMI. This figure shows a schematic view of a longitudinal section of an infarct-related artery at the level of the obstructive thrombus. Following rupture of a vulnerable plaque (bottom center), the coagulation cascade is activated, which ultimately leads to the deposition of fibrin strands; platelets are activated and begin to aggregate. Platelets that aggregate with incorporation of relatively few red cells form a white thrombus. The mesh of fibrin strands and platelet aggregates obstructs flow in the infarct-related artery. Pharmacologic reperfusion is a multipronged approach consisting of fibrinolytic agents that digest fibrin, anticoagulants that prevent the formation of thrombin and inhibit the activity of formed thrombin, and antiplatelet therapy. (Modified from Jackson SP: Arterial thrombosis—insidious, unpredictable, and deadly. *Nat Med* 17:1423, 2011.)

substantial reduction in mortality with aspirin alone and confusing and conflicting data regarding the risk-benefit ratio of heparin used as an adjunct to aspirin or in combination with aspirin and a fibrinolytic agent.¹ Nevertheless, a meta-analysis of trials in the fibrinolytic era suggested that for every 1000 patients treated with heparin versus aspirin alone, five fewer deaths ($P = 0.03$) and three fewer recurrent infarctions ($P = 0.04$) occur, but at the expense of three more major bleeding episodes ($P = 0.001$).⁸²

OTHER EFFECTS OF HEPARIN. Several angiographic studies have examined the role of heparin therapy in establishing and maintaining patency of the infarct-related artery in patients with STEMI. Although evidence favoring the use of heparin for enhancing patency of the infarct artery when a fibrin-specific fibrinolytic agent is prescribed is not conclusive, the suggestion of a mortality benefit and amelioration of left ventricular thrombi after STEMI indicates that use of heparin for at least 48 hours after fibrinolysis is prudent.¹

The most serious complication of anticoagulant therapy is bleeding (see Chapter 82), especially intracranial hemorrhage, when fibrinolytic agents are prescribed.⁸³ Major hemorrhagic events occur more frequently in patients with low body weight, advanced age, female sex, marked prolongation of the activated partial thromboplastin time (APTT) (>90 to 100 seconds), and performance of invasive procedures. Frequent monitoring of the APTT reduces the risk for major hemorrhagic complications in patients treated with heparin. It should be noted, however, that during the first 12 hours following fibrinolytic therapy, the APTT may be elevated as a result of the fibrinolytic agent alone (particularly if streptokinase is administered), thus making it difficult to accurately interpret the effects of a heparin infusion on the patient's coagulation status.

Newer Antithrombotic Agents

Potential disadvantages of unfractionated heparin include dependency on antithrombin III for inhibition of thrombin activity, sensitivity to platelet factor 4, inability to inhibit clot-bound thrombin, marked interpatient variability in therapeutic response, and the need for frequent monitoring of the APTT. Even with standardized weight-based dosing nomograms, less than 35% of initial APTT measurements are within the therapeutic range.⁸⁴ An effort to circumvent these disadvantages of unfractionated heparin has stimulated interest in the development of alternative anticoagulants.

HIRUDIN AND BIVALIRUDIN. In patients undergoing fibrinolysis, direct thrombin inhibitors such as hirudin or bivalirudin reduce the incidence of recurrent MI by 25% to 30% when compared with heparin but have not reduced mortality. In addition, both hirudin and bivalirudin cause higher rates of major bleeding than heparin does when used with fibrinolytic agents.⁸⁵ In contrast, when administered for a short period as an adjunct to primary PCI in the HORIZONS-AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial, bivalirudin (open label), versus heparin plus glycoprotein (GP) IIb/IIIa inhibitors, resulted in a reduced 30-day rate of major bleeding or major adverse cardiovascular events, including death, reinfarction, target vessel revascularization for ischemia, and stroke (RR, 0.76; 95% confidence interval [CI], 0.63 to 0.92; $P = 0.005$), driven by a significant 40% reduction in major bleeding. Importantly, treatment with bivalirudin significantly reduced mortality at 30 days and at 1 year (Fig. 52-15).⁸⁶ Bivalirudin

was associated with an increased early risk for stent thrombosis, thus demonstrating an early trade-off of bleeding and antithrombotic efficacy.⁸⁷ Additional studies have observed this increased early risk for stent thrombosis, with mixed results in terms of bleeding.^{87a,87b}

LOW-MOLECULAR-WEIGHT HEPARINS. Advantages of low-molecular-weight heparins (LMWHs) include a stable, reliable anticoagulant effect, high bioavailability permitting administration via the subcutaneous route, and a high anti-Xa-to-anti-IIa ratio producing blockade of the coagulation cascade in an upstream location and resulting in a marked decrement in thrombin generation. When compared with unfractionated heparin, the rate of early (60 to 90 minutes) reperfusion of the infarct artery, assessed either angiographically or by noninvasive means, is not enhanced by the administration of LMWH. Rates of reocclusion of the infarct artery, reinfarction, or recurrent ischemic events, however, appear to be reduced with LMWH.⁸⁸ This effect may underlie the significant reduction in recurrent MI with a strategy of extended anticoagulation with LMWHs, or a factor Xa antagonist versus standard therapy, in patients with STEMI undergoing fibrinolysis.

When compared with placebo, the LMWH reviparin significantly reduced the incidence of death, recurrent MI, or stroke at 30 days in 15,570 patients with STEMI, 73% of whom received a fibrinolytic (predominantly a non-fibrin-specific agent).⁸⁹ This important finding demonstrates not only that LMWHs are clinically effective for STEMI but also that a clinical anticoagulant therapy provides benefit as part of a pharmacologic reperfusion strategy in the fibrinolytic era.⁸⁹

Several trials have compared a LMWH with unfractionated heparin as part of a pharmacologic reperfusion strategy and demonstrated the LMWH to be superior.⁸⁹ In the ASSENT (Assessment of the Safety and Efficacy of a New Thrombolytic) 3 trial, enoxaparin (30-mg intravenous bolus, followed by subcutaneous injections of 1 mg/kg every 12 hours until discharge from the hospital)⁹⁰ reduced 30-day mortality, in-hospital reinfarction, or in-hospital refractory ischemia when compared with unfractionated heparin (RR, 0.74; 95% CI, 0.63 to 0.87). The rate of intracranial hemorrhage was similar with unfractionated heparin and enoxaparin (0.93% versus 0.88%; $P = 0.98$). The ExTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment—Thrombolysis in Myocardial Infarction [25]) trial tested in a double-blind, double-dummy design the hypothesis that a strategy of enoxaparin (adjusted for age and renal function) administered for the duration of the index

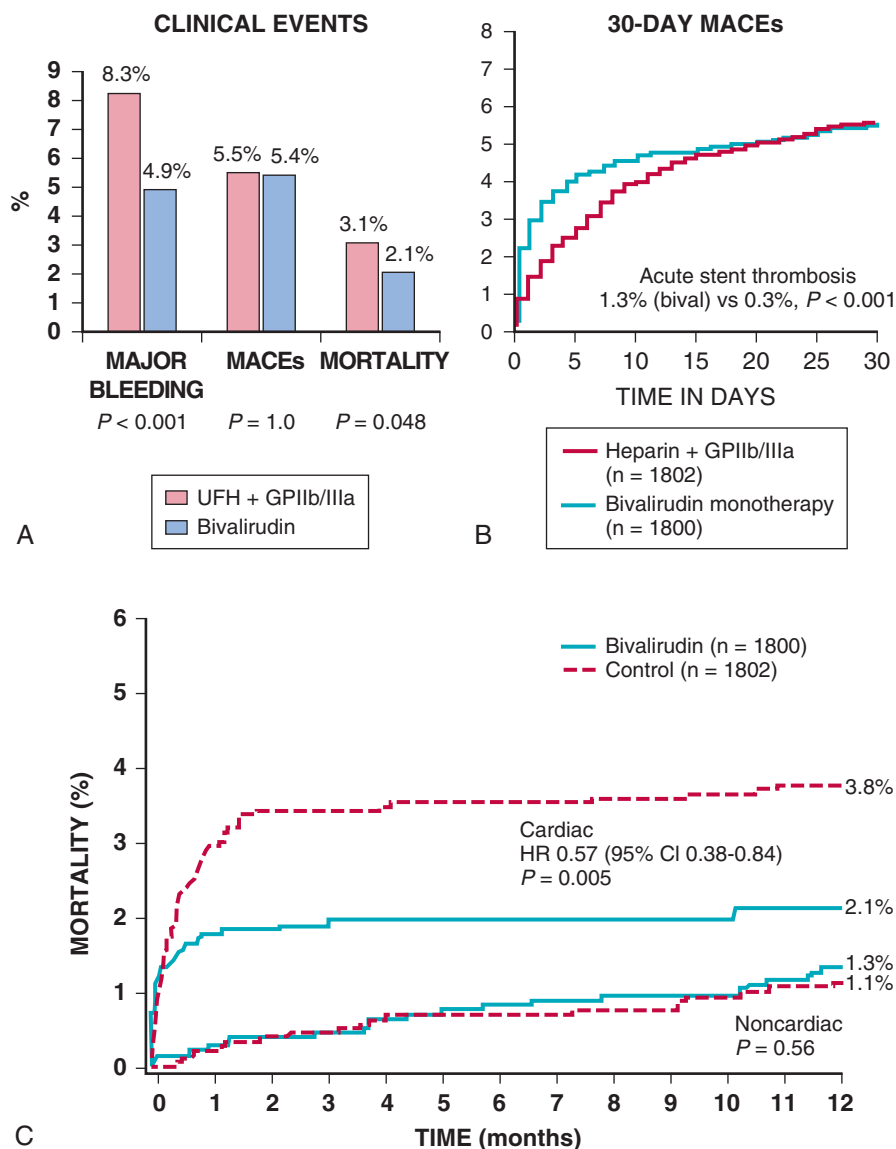

FIGURE 52-15 Results of an open-label randomized clinical trial comparing bivalirudin versus unfractionated heparin (UFH) and a GP IIb/IIIa receptor antagonist as adjunctive medical therapy to support primary PCI in patients with STEMI. **A**, Treatment with bivalirudin was associated with significantly lower rates of major bleeding and mortality at 30 days. **B**, Kaplan-Meier curves of the cumulative incidence of major adverse cardiac events (MACEs) did not differ between the two strategies at 30 days. **C**, Acute stent thrombosis during the first 24 hours was higher in patients treated with bivalirudin alone, but cardiovascular mortality was reduced in the bivalirudin group after 1 year of follow-up, thus providing strong evidence for this treatment strategy. (From Stone GW, Witzenbichler B, Guagliumi G, et al: Bivalirudin during primary PCI in acute myocardial infarction. *N Engl J Med* 358:2218, 2008; and Mehran R, Lansky AJ, Witzenbichler B: Bivalirudin in patients undergoing primary angioplasty for acute myocardial infarction (HORIZONS-AMI): 1-year results of a randomized controlled trial. *Lancet* 374:1149, 2009.)

hospitalization was superior to the conventional antithrombin strategy of administration of unfractionated heparin for 48 hours after fibrinolysis.⁹¹ The primary endpoint of death or recurrent nonfatal MI through 30 days was reduced by 17% ($P = 0.001$; Fig. 52-16A) with enoxaparin as compared with unfractionated heparin, with a 33% reduction ($P = 0.001$) in reinfarction and a nonsignificant favorable trend on overall mortality ($P = 0.11$). This improvement in recurrent MI was balanced against an increase in the incidence of major bleeding (1.4% and 2.1%, $P = 0.001$). In a meta-analysis of trials of LMWH versus unfractionated heparin, LMWH clearly reduced recurrent MI but with a pattern of increased bleeding (Fig. 52-16B).

PARENTERAL FACTOR Xa ANTAGONISTS. The OASIS-6 (Organization for the Assessment of Strategies for Ischemic Syndromes) trial evaluated the specific factor Xa antagonist fondaparinux (2.5 mg subcutaneously) in 12,092 patients with STEMI.⁹² The trial design

compared fondaparinux given for 8 days with placebo in patients when the treating physician thought that unfractionated heparin was not indicated (stratum I) and with unfractionated heparin for 48 hours when the treating physician thought that heparin was indicated (stratum II). Fondaparinux reduced the composite of death or reinfarction in stratum I (hazard ratio [HR], 0.79; 95% CI, 0.68 to 0.92), but not in stratum II (HR, 0.96; 95% CI, 0.81 to 1.13). Thus fondaparinux was superior to placebo (stratum I) but yielded results similar to those achieved with unfractionated heparin (stratum II). The outcome of patients in stratum II who underwent PCI tended to be worse when fondaparinux was used than when unfractionated heparin was used, probably because of an increased risk for catheter thrombosis.

ORAL FACTOR IIA AND FACTOR Xa ANTAGONISTS. See the section [Secondary Prevention of Acute Myocardial Infarction](#).

Recommendations for Anticoagulant Therapy

ANTICOAGULATION WITH FIBRINOLYSIS. Given the pivotal role of thrombin in the pathogenesis of STEMI, antithrombotic therapy remains an important intervention (see Fig. 55-14). A regimen of an intravenous unfractionated heparin bolus of 60 units/kg to a maximum of 4000 units, followed by an initial infusion at 12 units/kg/hr to a maximum of 1000 units/hr for 48 hours, adjusted to maintain the APTT at 1.5 to 2 times control (≈ 50 to 70 seconds), is effective in patients receiving fibrinolytic therapy. However, infusions of unfractionated heparin are cumbersome to administer and provide unreliable levels of anticoagulation that require frequent measurements of the APTT to adjust the infusion rate.⁹³ In addition, because of the risk for heparin-induced thrombocytopenia with prolonged administration of unfractionated heparin, alternative anticoagulant regimens are preferred if administered for longer than 48 hours.¹

Both the ExTRACT-TIMI 25 and OASIS-6 trials indicated that prolonged administration of an anticoagulant for the duration of hospitalization is beneficial when compared with the previous practice of administering unfractionated heparin only for 48 hours unless clear-cut indications for continued anticoagulation were present. Accordingly, patients managed with pharmacologic reperfusion therapy should receive anticoagulant therapy for a minimum

of 48 hours and preferably for the duration of hospitalization after STEMI, up to 8 days. Enoxaparin or fondaparinux is preferred when administration of an anticoagulant for longer than 48 hours is planned in patients with STEMI treated with a fibrinolytic.¹ Enoxaparin should be administered according to age, weight, and creatinine clearance and be given as an intravenous bolus, followed in 15 minutes by subcutaneous injection for the duration of the index hospitalization, up to 8 days or until revascularization. Fondaparinux should be administered as an initial intravenous dose, followed in 24 hours by daily subcutaneous injections if the estimated creatinine clearance is higher than 30 mL/min. If PCI is performed in a patient treated with fondaparinux, coadministration of an additional antithrombin agent with anti-factor IIa activity is required.

In patients with a known history of heparin-induced thrombocytopenia, bivalirudin in conjunction with streptokinase is a useful

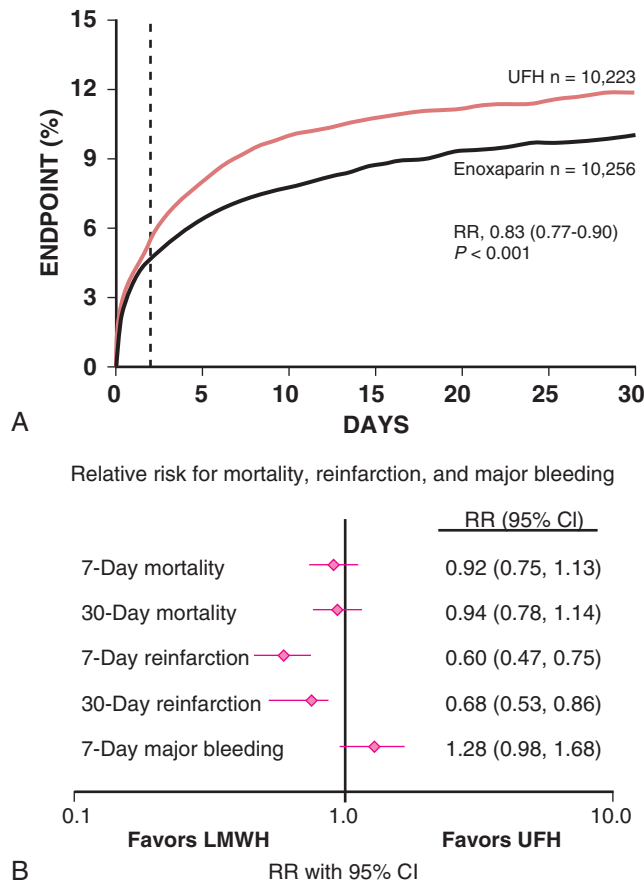

FIGURE 52-16 Comparison of enoxaparin with unfractionated heparin (UFH) as adjunctive therapy in patients with STEMI receiving fibrinolysis. **A**, Primary results from the EXTRACT-TIMI 25 trial showing that the rate of the primary endpoint (death or nonfatal MI) at 30 days was significantly lower in the enoxaparin group than in the UFH group (9.9% versus 12%, $P < 0.001$ by the log-rank test). The dashed vertical line indicates the comparison at day 2 (direct pharmacologic comparison), at which time a trend in favor of enoxaparin was seen. **B**, Results of a meta-analysis of seven randomized controlled clinical trials of LMWH versus UFH, including 27,577 patients with STEMI. Individual outcomes of all-cause death, reinfarction, and major bleeding through 7 days are shown. (From Antman EM, Morrow DA, McCabe CH, et al: Enoxaparin versus unfractionated heparin with fibrinolysis for ST-elevation myocardial infarction. *N Engl J Med* 354:1477, 2006; and Singh S, Bahekar A, Moinar J, et al: Adjunctive low molecular weight heparin during fibrinolytic therapy in acute ST-elevation myocardial infarction: A meta-analysis of randomized control trials. *Clin Cardiol* 32:358, 2009.)

alternative to heparin.¹ For patients who are referred for CABG, unfractionated heparin is the preferred antithrombin. When an alternative antithrombin has been used, it should be discontinued at a sufficiently long interval before surgery to avoid double anticoagulation when the patient enters the operating room and receives unfractionated heparin.

ADJUNCTIVE ANTICOAGULATION FOR PRIMARY PERCUTANEOUS CORONARY INTERVENTION (See Chapter 55). Either unfractionated heparin or bivalirudin is recommended as an anticoagulant to support primary PCI, with bivalirudin being preferred in patients at high risk for bleeding.^{1,86} Fondaparinux is not recommended as the sole anticoagulant in this setting.¹ LMWH has not had sufficient evaluation in primary PCI to formulate recommendations for treatment. Some investigators who have used enoxaparin to support primary PCI for STEMI administer 0.5 mg/kg intravenously at the time of the procedure.

PATIENTS TREATED WITHOUT REPERFUSION THERAPY. Treatment with an anticoagulant is reasonable, and agents shown to be more effective than unfractionated heparin in other groups with STEMI may be preferable. For example, in patients with STEMI not receiving reperfusion therapy, fondaparinux reduces the composite

of death or recurrent MI without an increase in severe bleeding when compared with placebo or unfractionated heparin.⁹⁴

Antiplatelet Therapy

Platelets play a major role in the response to disruption of coronary artery plaque, especially in the early phase of thrombus formation. Platelets are also activated in response to fibrinolysis, and platelet-rich thrombi are more resistant to fibrinolysis than are fibrin and erythrocyte-rich thrombi (see Fig. 52-14). Thus a sound scientific basis exists for inhibiting platelet aggregation in *all* patients with STEMI, regardless of the reperfusion management strategy. The agent most extensively tested has been aspirin, and treatment with aspirin and a second antiplatelet agent—such as clopidogrel, prasugrel, or ticagrelor—has become the standard of care for patients with STEMI.

Antiplatelet Therapy with Fibrinolysis

The ISIS-2 study was the largest trial of aspirin in patients with STEMI; it provided the single strongest piece of evidence that aspirin reduces mortality in such patients.⁹⁵ In contrast to the observations of a time-dependent mortality effect of fibrinolytic therapy, the reduction in mortality with aspirin was similar in patients treated within 4 hours (25% reduction in mortality), between 5 and 12 hours (21% reduction), and between 13 and 24 hours (21% reduction). An overall 23% reduction in mortality with aspirin occurred in ISIS-2 that was largely additive to the 25% reduction in mortality from streptokinase, so patients receiving both therapies experienced a 42% reduction in mortality. The reduction in mortality was as high as 53% in patients who received both aspirin and streptokinase within 6 hours of symptoms.

Obstructive platelet-rich arterial thrombi resist fibrinolysis and have an increased tendency for reocclusion after initial successful reperfusion in patients with STEMI. Despite inhibition of cyclooxygenase (COX) by aspirin, platelet activation leading to platelet aggregation and increased thrombin formation continues through thromboxane A_2 -independent pathways.²¹ Adding other antiplatelet agents to aspirin has benefited patients with STEMI. Inhibitors of the $P2Y_{12}$ adenosine diphosphate receptor help prevent the activation and aggregation of platelets. In the CLARITY-TIMI (Clopidogrel as Adjunctive Reperfusion Therapy—Thrombolysis in Myocardial Infarction) 28 trial, addition of the $P2Y_{12}$ inhibitor clopidogrel to background treatment with aspirin in patients with STEMI who were younger than 75 years and received fibrinolytic therapy reduced the risk for clinical events (death, reinfarction, stroke) and reocclusion of a successfully reperfused infarct artery (Fig. 52-17).⁹⁶ An ST Resolution (STRes) electrocardiographic sub-study from CLARITY-TIMI 28 provided insight into the mechanism of the benefit of clopidogrel in STEMI. No difference was seen in the rate of complete STRes between the clopidogrel and placebo groups at 90 minutes (38.4% versus 36.6%). When patients were stratified by STRes category, treatment with clopidogrel resulted in greater benefit in those with evidence of early STRes, with greater odds of having an open artery at late angiography in patients with partial (odds ratio [OR], 1.4; $P = 0.04$) or complete (OR, 2; $P = 0.001$) STRes, but no improvement in those with no STRes evident at 90 minutes (OR, 0.89; $P = 0.48$) (P for interaction = 0.003). Clopidogrel was also associated with a significant reduction in the odds for in-hospital death or MI in patients who achieved partial (OR, 0.30; $P = 0.003$) or complete STRes at 90 minutes (OR, 0.49; $P = 0.056$), whereas clinical benefit was not apparent in patients who had no STRes (OR, 0.98; $P = 0.95$) (P for interaction = 0.027). Thus it appears that clopidogrel did not increase the rate of complete opening of occluded infarct arteries when fibrinolysis was administered but was highly effective in preventing reocclusion of an initially reperfused infarct artery.

In COMMIT (Clopidogrel and Metoprolol in Myocardial Infarction Trial), 45,852 patients with suspected MI were randomly assigned to clopidogrel, 75 mg/day (without a loading dose), or placebo in addition to aspirin, 162 mg/day (Fig. 52-17).⁹⁶ Patients in the clopidogrel group had a lower rate of the composite endpoint of death, reinfarction, or stroke (9.2% versus 10.1%; $P = 0.002$). They also had a significantly lower rate of death (7.5% versus 8.1%; $P = 0.03$). No excessive bleeding with clopidogrel occurred in this trial.

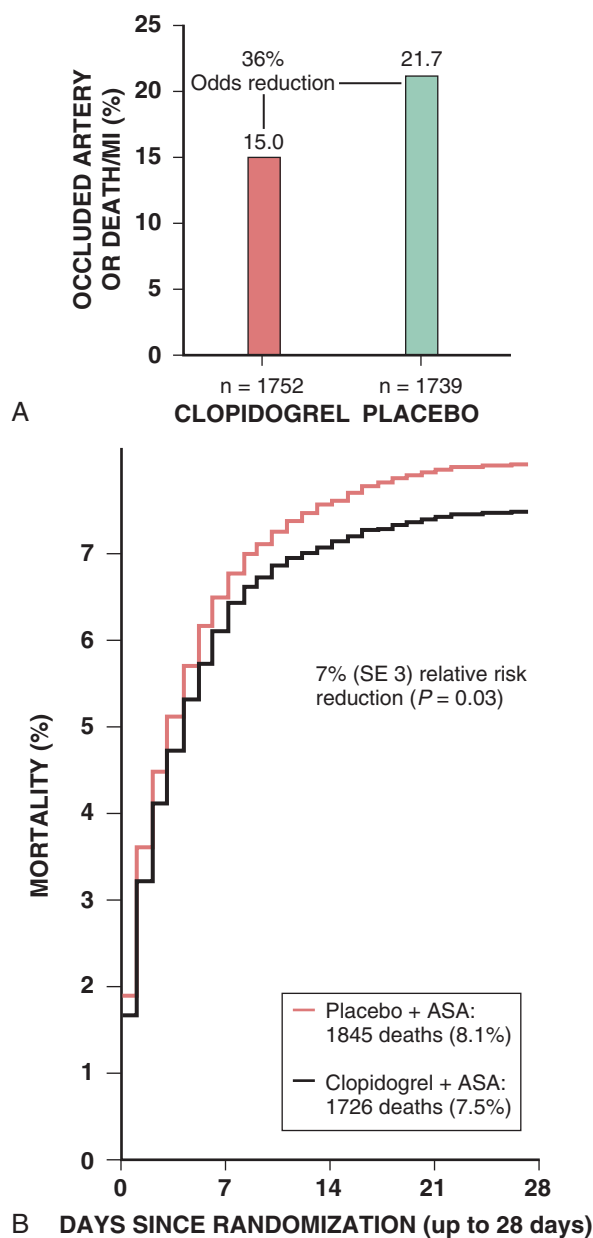

FIGURE 52-17 Impact of the addition of clopidogrel to aspirin (ASA) in patients with STEMI. **A**, Effects of the addition of clopidogrel in patients receiving fibrinolysis for STEMI. Patients in the clopidogrel group ($n = 1752$) had a 36% reduction in the odds of dying, sustaining a recurrent infarction, or having an occluded infarct artery in comparison to the placebo group ($n = 1739$) in the CLARITY-TIMI 28 trial. **B**, Effect of the addition of clopidogrel on in-hospital mortality after STEMI. These time-to-event curves show a 0.6% reduction in mortality in the group receiving clopidogrel plus aspirin ($n = 22,961$) versus placebo plus aspirin ($n = 22,891$) in the COMMIT trial. (**A**, Modified from Sabatine MS, Cannon CP, Gibson, CM, et al: Addition of clopidogrel to aspirin and fibrinolytic therapy for myocardial infarction with ST-segment elevation. *N Engl J Med* 352:1179, 2005; **B**, modified from Chen ZM, Jiang LX, Chen YP, et al: Addition of clopidogrel to aspirin in 45,852 patients with acute myocardial infarction: Randomised placebo-controlled trial. *Lancet* 366:1607, 2005.)

Combination Pharmacologic Reperfusion

Several studies evaluated the combination of platelet GP IIb/IIIa inhibitors and fibrinolytics. Trials of GP IIb/IIIa inhibitors combined with either full or reduced doses of fibrinolytics showed improvements in reperfusion, including myocardial perfusion as reflected in enhanced ST-segment resolution and faster angiographic frame counts. However, subsequent large outcomes trials revealed no significant effect on survival and reductions in reinfarction that were outweighed

by the increases in bleeding.⁹⁰ The combination of a GP IIb/IIIa inhibitor and a fibrinolytic as a pharmacologic reperfusion regimen is therefore not recommended.¹

Antiplatelet Therapy for Percutaneous Coronary Intervention in ST-Elevation Myocardial Infarction (See Chapter 55)

All patients with STEMI should receive aspirin as soon as possible after initial encounter in the absence of contraindications. Adding the P2Y₁₂ inhibitor clopidogrel to aspirin appears to offer additional benefit in patients undergoing PCI after STEMI. An analysis of the subgroup of patients who underwent PCI in the CLARITY-TIMI 28 trial showed that pretreatment with clopidogrel significantly reduced the incidence of cardiovascular death, MI, or stroke following PCI (3.6% versus 6.2%; $P = 0.008$).^{1,97} Pretreatment with clopidogrel also reduced the incidence of MI or stroke before PCI (4% versus 6.2%; $P = 0.03$). There was no significant excess in rates of TIMI major or minor bleeding (2% versus 1.9%; $P = 0.99$). As part of the PCI-CLARITY (PCI-Clopidogrel as Adjunctive Reperfusion Therapy) study, the investigators performed a meta-analysis of PCI-CLARITY, PCI-CURE (PCI-Clopidogrel in Unstable angina to prevent Recurrent Events), and CREDO (Clopidogrel for the Reduction of Events During Observation) and found that pretreatment with clopidogrel significantly reduced the risk for 30-day cardiovascular death or MI. A subsequent meta-analysis included data from randomized trials and registries of patients with CAD (stable or with an ACS) undergoing catheterization for potential revascularization to evaluate the association between pretreatment with clopidogrel and outcomes after PCI. Higher-risk STEMI patients had a lower risk for major coronary events with clopidogrel pretreatment, but not a reduction in mortality or an increase in bleeding.⁹⁸ Regarding dose, in CURRENT-OASIS-7 (Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events—Seventh Organization to Assess Strategies in Ischemic Syndromes), which included a population in which 29% had STEMI, doubling the standard dose of clopidogrel (loading dose of 600 mg, daily dose of 150 mg) for the first 7 days did not improve outcome in the overall ACS population referred for an invasive strategy, but there was benefit in ACS patients who actually underwent PCI.^{99,100}

In patients undergoing either primary PCI or delayed PCI after initial therapy for STEMI, the more potent P2Y₁₂ inhibitor prasugrel has been superior to clopidogrel in reducing the risk for cardiovascular death, MI, or stroke.¹⁰¹ In the subgroup of patients with STEMI enrolled in TRITON-TIMI 38 (TRial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis In Myocardial Infarction) ($N = 3534$), this endpoint was lowered by 32% at 30 days with prasugrel as compared with aspirin (6.5% versus 9.5%; $P = 0.0017$) and by 21% at 15 months (10.0% versus 12.4%; $P = 0.022$) (Fig. 52-18).¹⁰² Prasugrel reduced definite or probable stent thrombosis by 42% when compared with clopidogrel.¹⁰² Analogously, in the PLATO (Platelet Inhibition and Patient Outcomes) trial, when compared with clopidogrel, treatment with the reversible P2Y₁₂ inhibitor ticagrelor in patients with STEMI undergoing primary PCI ($N = 7544$) tended to reduce the primary endpoint of cardiovascular death, recurrent MI, or stroke by 13%, a magnitude similar to that for the overall trial population (Fig. 52-18); there was a 26% reduction in definite or probable stent thrombosis and an 18% reduction in all-cause mortality also occurred.¹⁰³ A discussion of the use of GP IIb/IIIa inhibitors as part of adjunctive therapy for patients with STEMI undergoing PCI is presented in Chapter 55.

Recommendations for Antiplatelet Therapy

Patients who have not taken aspirin before the development of STEMI should chew non-enteric-coated aspirin, and the dose should be 162 to 325 mg initially. During the maintenance phase of antiplatelet therapy following STEMI, the dose of aspirin is preferably reduced to 75 to 162 mg to minimize the risk for bleeding.¹ Lower doses are preferable because of the increased risk for bleeding with higher

FIGURE 52-18 **A**, Efficacy of prasugrel in the subgroup of patients with STEMI enrolled in a randomized clinical trial of prasugrel versus clopidogrel in patients undergoing PCI after an ACS. Treatment with prasugrel was associated with a 21% relative reduction in the risk for cardiovascular (CV) death, MI, or stroke during 15 months of follow-up. **B**, Major bleeding (TIMI non-CABG) increased with prasugrel in the trial overall, but not in patients with STEMI. **C**, Efficacy results for ticagrelor (versus clopidogrel) in patients with STEMI enrolled in the PLATO trial. Ticagrelor reduced the primary endpoint (incidence of MI, stroke, or vascular death) versus clopidogrel from 11.0% to 9.3% (HR, 0.85; 95% CI, 0.74 to 0.97; $P = 0.02$). **D**, Rates of major bleeding (TIMI non-CABG) are shown. (**A, B**, From Montalescot G, Wiviott SD, Braunwald E, et al: Prasugrel compared with clopidogrel in patients undergoing percutaneous coronary intervention for ST-elevation myocardial infarction [TRITON-TIMI 38]: Double-blind, randomised controlled trial. *Lancet* 373:723, 2009; **C, D**, from Steg PG, James S, Harrington RA, et al: Ticagrelor versus clopidogrel in patients with ST-elevation acute coronary syndromes intended for reperfusion with primary percutaneous coronary intervention: A Platelet Inhibition and Patient Outcomes (PLATO) trial subgroup analysis. *Circulation* 122:2131, 2010.)

doses reported in several studies; the CURRENT-OASIS 7 trial did not find differences in terms of efficacy or safety in STEMI patients randomly assigned to 81 versus 325 mg of aspirin. If true aspirin allergy is present, other antiplatelet agents such as clopidogrel or ticlopidine can be substituted.

The addition of a P2Y₁₂ inhibitor to aspirin is warranted in most patients with STEMI.¹ Based on the results of the COMMIT and CLARITY-TIMI 28 trials, clopidogrel, 75 mg/day orally, is an option for all patients with STEMI regardless of whether they receive fibrinolytic therapy, undergo primary PCI, or do not receive reperfusion therapy. The data available suggest that a loading dose of 300 mg of clopidogrel should be given to patients younger than 75 years who receive fibrinolytic therapy. Data are insufficient in elderly patients to recommend a loading dose in those 75 years or older who receive a fibrinolytic.

When primary PCI is the mode of reperfusion therapy, an oral loading dose of 600 mg of clopidogrel before stent implantation is an established treatment, followed by 75 mg daily.^{1,6} Notably, interpatient variability in the response to clopidogrel can occur, and individuals with lesser degrees of platelet inhibition are at increased risk for death and ischemic complications.¹⁰⁴ One potential source of this variability is the metabolism of clopidogrel, which is a prodrug that requires absorption and biotransformation to become an active antiplatelet compound. Cytochrome P-450 (CYP) enzymes play a role in the metabolism, and carriers of particular genetic variants in *CYP2C19* (~30% of the population) have lower active clopidogrel metabolite levels, diminished platelet inhibition, and higher rates of adverse

cardiovascular events than do noncarriers in the setting of PCI.¹⁰⁵⁻¹⁰⁷

The response to clopidogrel may also vary as a function of a patient's clinical characteristics, such as age or diabetic status.¹⁰⁴

Prasugrel and ticagrelor generally achieve greater degrees of platelet inhibition than clopidogrel does and can be used to treat patients with STEMI. On the basis of the results of TRITON-TIMI 38, prasugrel administered as an oral loading dose of 60 mg and 10 mg daily thereafter demonstrated benefit in patients with STEMI, but should not be used in patients with a history of cerebrovascular disease who are at higher risk for life-threatening bleeding.^{101,102} Ticagrelor also reduced cardiovascular events when compared with clopidogrel, and in PLATO, ticagrelor was administered as an oral loading dose of 180 mg and 90 mg twice daily.^{103,108} When using ticagrelor, the recommended maintenance dose of aspirin is 81 mg daily.¹

HOSPITAL MANAGEMENT

Coronary Care and Intermediate Care Units

Development of the coronary care unit (CCU) has facilitated continuous monitoring of cardiac rhythm by highly trained nurses with the skills and authority to initiate immediate treatment of arrhythmias in the absence of physicians and with the availability of specialized equipment (defibrillators, pacemakers) and drugs.¹⁰⁹ The clustering of patients with STEMI in the CCU greatly enhanced efficient use of the trained personnel, facilities, and equipment to improve patient outcomes.¹⁰⁹ These benefits of geographic clustering contribute to the

optimal care of patients with STEMI, and in some hospitals, such care can be provided in “intermediate care” telemetry units with well-trained staff outside the CCU. Such intermediate care units, when equipped with continuous electrocardiographic monitoring and resuscitation equipment, may be appropriate for initial admission of patients with a low risk for mortality from STEMI. This strategy has proved cost-effective and may reduce CCU use by a third, shorten hospital stays, and have no deleterious effect on patients’ recovery.¹

With increasing attention directed to limitations on resources and to the economic impact of intensive care, the proportion of appropriately selected patients with STEMI cared for in an intermediate care unit is likely to increase. Nevertheless, a dedicated CCU is the environment most often used to provide care for patients with STEMI, and it plays a pivotal role in the management of patients with major complications of STEMI, who may require treatment of refractory arrhythmias, use of invasive hemodynamic monitoring, or mechanical circulatory support.¹¹⁰ Facilities in which patients can undergo diagnostic and therapeutic angiographic procedures are often integrated into the structure of a coronary care team.¹¹¹ The capacity for early detection of problems following STEMI and the social and educational benefits of grouping such patients together strongly argue for continued use of CCUs and intermediate care units with experienced multidisciplinary staff.

In patients with STEMI managed in a CCU, those with an uncomplicated status, such as patients without congestive heart failure, hypotension, heart block, hemodynamically compromising ventricular arrhythmias, or persistent ischemic-type discomfort, can be safely transferred out of the CCU within 24 to 36 hours. In patients with complicated STEMI, the duration of the CCU stay should be dictated by the need for “intensive” care—that is, hemodynamic monitoring, close nursing supervision, intravenous vasoactive drugs, and frequent changes in the medical regimen.

General Measures

The managing clinical staff should be sensitive to patient concerns about prognosis and future productivity. A calm, quiet atmosphere can help allay anxiety and reduce sympathetic tone, thereby potentially reducing hypertension, tachycardia, and arrhythmias. Use of anxiolytic medications may be appropriate in some cases. To reduce the risk for nausea and vomiting early after infarction and to decrease the risk for aspiration, patients should receive either nothing by mouth or a clear liquid diet during the first 4 to 12 hours after admission. Thereafter, dietary intervention is an important component of an overall strategy for secondary prevention (see [Chapters 42 and 46](#)).

The results of laboratory tests should be scrutinized for any derangements potentially contributing to arrhythmias, such as hypoxemia, hypovolemia, or disturbances in acid-base balance or electrolytes. Delirium can be provoked by medications frequently used in the hospital, including antiarrhythmic drugs, H₂ blockers, narcotics, and beta blockers. Use of potentially offending agents should be discontinued in patients with an abnormal mental status. Haloperidol, a butyrophenone, can be used safely in patients with STEMI. Stool softeners should be considered to prevent constipation and straining.

Physical Activity

In the absence of complications, stabilized patients with STEMI need not be confined to bed for more than 12 hours, and unless they are hemodynamically compromised, they may use a bedside commode shortly after admission. Progression of activity should be individualized depending on the patient’s clinical status, age, and physical capacity. In patients without hemodynamic compromise, early mobilization—including sitting in a chair, standing, and walking around the bed—does not usually cause important changes in heart rate, blood pressure, or pulmonary wedge pressure. As long as the blood pressure and heart rate are monitored, early mobilization offers considerable psychological and physical benefit without any clear medical risk.

Pharmacologic Therapy

Beta Blockers

Use of beta blockers for the treatment of patients with STEMI can cause both immediate effects (when the drug is given early in the course of infarction) and long-term effects (secondary prevention). Immediate intravenous administration of beta blockers reduces the cardiac index, heart rate, and blood pressure.¹¹² The net effect is a reduction in myocardial oxygen consumption per minute and per beat. Favorable effects of acute intravenous administration of beta blockers on the balance of myocardial oxygen supply and demand are reflected in reductions in chest pain, in the proportion of patients with threatened infarction in whom STEMI actually evolves, and in the development of ventricular arrhythmias. Because beta-adrenergic blockade diminishes circulating levels of free fatty acids by antagonizing the lipolytic effects of catecholamines and because elevated levels of fatty acids augment myocardial oxygen consumption and probably increase the incidence of arrhythmias, these metabolic actions of beta blockers may also benefit the ischemic heart. As noted earlier, because early administration of intravenous beta blockers can cause detrimental effects in some patients, the present guidelines omit this therapy for most patients.¹

More than 52,000 patients have been randomly assigned to treatment in clinical trials studying beta-adrenergic blockade for acute MI.¹ These trials cover a range of beta blockers and timing of administration and were largely conducted in the era before reperfusion strategies were developed for STEMI. Data available in the pre-reperfusion era suggested favorable trends toward a reduction in mortality, reinfarction, and cardiac arrest. In the reperfusion era, adding an intravenous beta blocker to fibrinolytic therapy was not associated with a reduction in mortality but helped reduce the rate of recurrent ischemic events. Concern arose regarding the potential risk of provoking cardiogenic shock if early intravenous followed by oral beta-adrenergic blockade was routinely administered to all patients with STEMI. The largest trial of beta blockade in patients with acute MI was COMMIT, which randomly assigned 45,852 patients within 24 hours of MI to metoprolol given as sequential intravenous boluses of 5 mg up to 15 mg, followed by 200 mg/day orally, or to placebo.¹ The rate of the composite endpoint of death, reinfarction, or cardiac arrest in the metoprolol group (9.4%) did not differ from that in the placebo group (9.9%). Significant reductions occurred in reinfarction and episodes of VF in the metoprolol group, which translated into 5 fewer events for each of these endpoints per 1000 patients treated; yet there were 11 more episodes of cardiogenic shock in the metoprolol group per 1000 patients treated. Risk for the development of cardiogenic shock (which was recorded as part of the COMMIT protocol in contrast to earlier studies) was greatest in patients with moderate to severe left ventricular dysfunction (Killip class II or greater).

The combined results of the low-risk patients from COMMIT and data from earlier trials provide an overview of the effects of early intravenous therapy followed by oral therapy with beta blockers ([Fig. 52-19](#)). A 13% reduction occurred in all-cause mortality (7 lives saved per 1000 patients treated), along with a 22% reduction in reinfarction (5 fewer events per 1000 patients treated) and a 15% reduction in VF or cardiac arrest (5 fewer events per 1000 patients treated). To achieve these benefits safely, early administration of beta blockers to patients with relative contraindications should be avoided, as outlined in [Table 52-7](#).

Recommendations

Given the evidence of a benefit of early administration of beta-blocking agents for STEMI, patients without a contraindication, irrespective of the administration of concomitant fibrinolytic therapy or performance of primary PCI, should receive *oral* beta blockers within the first 24 hours ([Table 52-7](#)). Prompt intravenous administration of beta-blocking therapy to patients with STEMI is also reasonable if a tachyarrhythmia or hypertension is present, in the absence of signs of heart failure/low output, increased risk for the development of

FIGURE 52-19 Meta-analysis of the effects of intravenous and then oral beta blocker therapy on death, reinfarction, and cardiac arrest during the scheduled treatment periods in 26 small randomized trials, MIAMI, ISIS-1, and the low-risk subset of COMMIT. For COMMIT, data are included only for patients with a systolic blood pressure higher than 105 mm Hg, a heart rate greater than 65 beats/minute, and Killip class I (as in MIAMI7). Five small trials included in the ISIS-1 report did not have any data on reinfarction. In the ISIS-1 trial, data on reinfarction in the hospital were available for the last three quarters of the study and involved 11,641 patients. ORs in each (blue squares with the area proportional to the number of events) were determined by comparing outcomes in patients allocated to beta blocker therapy with those in patients allocated to control, along with 99% CIs (horizontal lines). Overall ORs and 95% CIs are plotted by the diamonds, with value and significance given alongside. (From Chen ZM, Pan HC, Chen YP, et al: Early intravenous then oral metoprolol in 45,852 patients with acute myocardial infarction: Randomised placebo-controlled trial. *Lancet* 366:1622, 2005.)

TABLE 52-7 Recommendations for Beta Blocker Therapy for ST-Elevation Myocardial Infarction

RECOMMENDATION	COR	LOE
Oral beta blockers should be initiated in the first 24 hours in patients with STEMI who do not have any of the following: Signs of heart failure or evidence of a low-output state Increased risk for cardiogenic shock*: Age > 70 years Systolic blood pressure <120 mm Hg Sinus tachycardia >110 beats/min or heart rate <60 beats/min Increased time since the onset of symptoms of STEMI Other contraindications to use of oral beta blockers: PR interval longer than 0.24 second Second- or third-degree heart block Active asthma or reactive airways disease	I	B
Beta blockers should be continued during and after hospitalization for all patients with STEMI and no contraindications to their use.	I	B
Patients with initial contraindications to the use of beta blockers in the first 24 hours after STEMI should be reevaluated to determine their subsequent eligibility.	I	C
It is reasonable to administer IV beta blockers at initial encounter to patients with STEMI and no contraindications to their use who are hypertensive or have ongoing ischemia.	IIa	B

*The greater the number of risk factors present, the higher the risk for development of cardiogenic shock.

COR = class of recommendation; LOE = level of evidence.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e78, 2013.

shock, indicators of high risk for the development of shock, or other relative contraindications to beta blockers.¹

Beta blockers are especially helpful in STEMI patients with significant residual unrevascularized CAD and evidence of recurrent ischemia or tachyarrhythmias early after the onset of infarction.¹¹³ If adverse effects of beta blockers develop or if patients have complications of infarction that are contraindications to beta blockade, such as heart failure or heart block, beta blockers should be withheld. Unless there are contraindications (Table 52-7), beta blockade probably should be continued in patients in whom STEMI develops. Moreover, patients who initially have contraindications to a beta blocker, such as heart failure, should be reevaluated with respect to their candidacy for such therapy after 24 hours.¹

Selection of Beta Blockers

Favorable effects have been reported with metoprolol, atenolol, carvedilol, timolol, and alprenolol; these benefits probably occur with propranolol and with esmolol, an ultrashort-acting agent, as well. In the absence of any favorable evidence supporting the benefit of agents with intrinsic sympathomimetic activity, such as pindolol and oxprenolol, and with some unfavorable evidence for these agents in secondary prevention, beta blockers with intrinsic sympathomimetic activity should probably not be chosen for treatment of STEMI. The CAPRICORN (Carvedilol Post infarction survival COntrol in left ventricular dysfunction) trial randomly assigned 1959 patients with MI and systolic dysfunction (ejection fraction <40%) to carvedilol or placebo in addition to contemporary pharmacotherapy, including angiotensin-converting enzyme (ACE) inhibitors in 98% of patients. All-cause mortality was reduced over a mean follow-up of 1.3 years by 23% with carvedilol in comparison to placebo ($P = 0.031$), with a similar pattern noted during the first 30 days.¹¹⁴ Thus CAPRICORN confirmed the benefit of administration of a beta blocker in addition to ACE inhibitor therapy in patients with transient or sustained left ventricular dysfunction after MI.

Occasionally, clinicians may wish to proceed with therapy with a beta blocker even in patients with relative contraindications, such as a history of mild asthma, mild bradycardia, mild heart failure, or first-degree heart block. In this situation a trial of esmolol may help determine whether the patient can tolerate beta-adrenergic blockade. Because the hemodynamic effects of this drug, which has a half-life of 9 minutes, disappear in less than 30 minutes, it offers an advantage over longer-acting agents when the risk for complications with a beta blocker is relatively high.

Inhibition of the Renin-Angiotensin-Aldosterone System

The rationale for inhibition of the renin-angiotensin-aldosterone system (RAAS) includes experimental and clinical evidence of a favorable impact on ventricular remodeling, improvement in hemodynamics, and a reduction in the incidence of congestive heart failure. Unequivocal evidence from randomized, placebo-controlled trials has shown that ACE inhibitors reduce the rate of mortality from STEMI.¹ These trials can be grouped into two categories. The first group *selected* MI patients for randomization on the basis of features indicative of increased mortality, such as left ventricular ejection fraction lower than 40%, clinical signs and symptoms of congestive heart failure, anterior location of infarction, and abnormal wall motion score index (Fig. 52-20). The second group consisted of *unselected* trials that randomized all patients with MI provided that they had a minimum systolic pressure of approximately 100 mm Hg (ISIS-4, GISSI-3 [Gruppo Italiano per lo Studio della Sopravvivenza nell'infarto Miocardico], CONSENSUS II [Cooperative New Scandinavian Enalapril Survival Study II], and the Chinese Captopril Study) (Fig. 52-21). With the exception of the SMILE (Survival of Myocardial Infarction Long-Term Evaluation) study, all the selective trials initiated ACE inhibitor therapy between 3 and 16 days after MI and maintained it for 1 to 4 years, whereas the unselective trials all initiated treatment within the first 24 to 36 hours and maintained it for only 4 to 6 weeks.

A consistent survival benefit was observed in all the trials already noted, except for CONSENSUS II, the one study that used an

FIGURE 52-20 Effect of ACE inhibitors on mortality after MI—results from long-term trials. (From Gornik H, O’Gara PT: *Adjunctive medical therapy*. intravenous preparation early in the course of MI. An estimate of the mortality benefit of ACE inhibitors in the unselective trials with a short duration of therapy was 5 lives saved per 1000 patients treated. Analysis of these unselective short-term trials indicates that approximately a third of the lives saved occurred within the first 1 to 2 days. Certain subgroups, such as patients with anterior infarction, showed proportionately greater benefit with the early administration (11 lives saved per 1000) of ACE inhibitors. Not unexpectedly, greater survival benefits of 42 to 76 lives saved per 1000 patients treated were obtained in the selective trials with a long duration of therapy. Of note, a general 20% reduction in the risk for death attributable to ACE inhibitor treatment occurred in the selective trials. The reduction in mortality with ACE inhibitors was accompanied by significant reductions in the development of heart failure, thus supporting the underlying pathophysiologic rationale for administering this class of drugs to patients with STEMI. In addition, some data suggest that chronic administration of ACE inhibitors after STEMI reduces the incidence of ischemic events, including recurrent infarction and the need for coronary revascularization.²⁹

The mortality benefits of ACE inhibitors are additive to those achieved with aspirin and beta blockers. The benefits of ACE inhibition appear to be a class effect inasmuch as several agents have been associated with reduced mortality and morbidity. To replicate these benefits in clinical practice, however, physicians should select a specific agent and prescribe the drug according to the protocols used in the successful clinical trials reported to date.¹¹⁵

The major contraindications to the use of ACE inhibitors in patients with STEMI include hypotension in the setting of adequate preload, known hypersensitivity, and pregnancy. Adverse reactions include hypotension, especially after the first dose, and intolerable cough; much less commonly, angioedema can occur.

Other Therapies

Magnesium

A functional deficit in available magnesium may develop in patients with STEMI. Because of the risk for cardiac arrhythmias when electrolyte deficits are present in the early phase of infarction, patients with STEMI should have their serum magnesium measured on admission. We advocate repleting magnesium deficits to maintain a serum magnesium level of 2 mEq/liter or greater. In the presence of hypokalemia, the serum magnesium level should be rechecked and repleted if necessary because it is often difficult to correct a potassium deficit in the presence of a concurrent magnesium deficit. There is no indication for routine intravenous administration of magnesium to patients with STEMI.

Glucose Control During ST-Elevation Myocardial Infarction (See also Chapter 61)

During the acute phase of STEMI, catecholamine levels increase in both the blood and ischemic myocardium. Insulin levels remain low, whereas cortisol, glucagon, and free fatty acid levels increase. These factors may contribute to an elevation in the blood glucose level, which should be measured routinely on admission. Intensive insulin therapy to strictly control blood glucose is no longer recommended routinely for patients with MI.¹¹⁸ Blood glucose levels should be maintained below 180 mg/dL if possible while avoiding hypoglycemia.¹

Routine administration of infusions of glucose-insulin-potassium (GIK) to patients with STEMI was proposed to reduce mortality. A series of small trials suggested that GIK infusions were beneficial, but the CREATE-ECLA (Clinical Trial of MEtabolic Modulation in Acute Myocardial Infarction Treatment Evaluation-Estudios Cardiologicos Latinoamerica) investigators randomly assigned 20,201 patients with STEMI (83% of whom received reperfusion therapy) to GIK or placebo and found no impact on mortality (30-day mortality, 9.7% in control patients and 10% in GIK patients).^{119,120} In addition, prehospital administration of GIK did not improve the primary endpoint of progression to MI in patients with ACSs.¹²¹ Thus in the contemporary era of management of STEMI in which other effective therapies (reperfusion, aspirin, ACE inhibitors) are administered, routine use of GIK infusions appears to have no benefit.

Other Agents

Multiple adjunctive pharmacotherapies to prevent inflammatory damage in the infarct zone have been investigated but have not shown clinical benefit.¹²² For example, pexelizumab, a monoclonal antibody against the C5 component of complement, had no effect on infarct size in patients with STEMI treated with either fibrinolytics or PCI or on mortality in patients treated with primary PCI.¹²³ Intravenous administration of adenosine to reduce myocardial injury in patients with STEMI has been studied. Although administration of high-dose adenosine has been associated with a reduction in infarct size, neither high-dose nor low-dose adenosine improves clinical outcomes such as death or the development of heart failure when compared with placebo.¹²⁴

HEMODYNAMIC DISTURBANCES

Hemodynamic Assessment

Patients with clinically uncomplicated STEMI do not require invasive hemodynamic monitoring because clinical evaluation can be used to assess the status of the circulation. Routine assessments in patients with STEMI should include monitoring of the heart rate and rhythm, repeated measurement of systemic arterial pressure by cuff, repeated auscultation of the lung fields for pulmonary congestion, measurement of urine output, examination of the skin for evidence of the adequacy of perfusion, and monitoring for hypoxemia.

In patients with STEMI who have clinical signs and symptoms of heart failure, assessment of the degree of hemodynamic compromise is important. Central venous pressure reflects right rather than left

ventricular function. Right ventricular function—and therefore systemic venous pressure—may be normal or almost so in patients with significant left ventricular failure. Conversely, patients with right ventricular failure caused by right ventricular infarction or pulmonary embolism may exhibit elevated right atrial and central venous pressure despite normal left ventricular function. Low values for right atrial and central venous pressure imply hypovolemia, whereas elevated right atrial pressure usually results from right ventricular failure secondary to left ventricular failure, pulmonary hypertension, right ventricular infarction, or less commonly, tricuspid regurgitation or pericardial tamponade.

In patients with complicated STEMI it may be useful to establish invasive monitoring with an intra-arterial catheter and a pulmonary artery catheter for measurement of pulmonary artery, pulmonary artery occlusive (equivalent to pulmonary wedge), and right atrial pressure, as well as cardiac output. In patients with hypotension, a Foley catheter provides accurate and continuous measurement of urine output.

Monitoring of Pulmonary Artery Pressure

Table 52-8 describes circumstances when to consider invasive monitoring. Patients most likely to benefit from pulmonary artery catheter monitoring include those whose STEMI is complicated by (1) hypotension that is not easily corrected by fluid administration, (2) hypotension in the presence of congestive heart failure, (3) hemodynamic compromise severe enough to require intravenous vasopressors or vasodilators or intra-aortic balloon counterpulsation, (4) mechanical lesions (or suspected ones) such as severe mitral regurgitation and a ruptured ventricular septum, and (5) right ventricular infarction.¹²⁵ Other possible indications for hemodynamic monitoring include assessment of the effects of mechanical ventilation, differentiating pulmonary disease from left ventricular failure as the cause of hypoxemia, and management of septic shock (**Table 52-8**).

Before inserting a pulmonary artery catheter into a patient with STEMI, the physician must believe that the potential benefit of the information that can be obtained outweighs any potential risks. Accumulating evidence from settings other than STEMI suggests that invasive hemodynamic monitoring does not improve outcomes.¹²⁶ Major complications from pulmonary artery catheters are not common, but severe problems can occur—including sepsis, pulmonary infarction, and pulmonary artery rupture. Minimized duration of catheterization and strict adherence to aseptic technique can diminish the risk. Using antiseptic-impregnated dressings can also reduce catheter-related bloodstream infections.¹²⁷ Noninvasive methods of determination of cardiac output, such as pulse contour analysis and thoracic electrical bioimpedance, are also available.^{128,129}

TABLE 52-8 Indications for Hemodynamic Monitoring in Patients with ST-Elevation Myocardial Infarction

Management of complicated acute MI
Hypovolemia versus cardiogenic shock
Ventricular septal rupture versus acute mitral regurgitation
Severe left ventricular failure
Right ventricular failure
Refractory ventricular tachycardia
Difficulty differentiating severe pulmonary disease from left ventricular failure with available noninvasive data
Assessment of cardiac tamponade
Assessment of therapy in selected individuals
Afterload reduction in patients with severe left ventricular failure
Inotropic agent therapy
Beta-blocking agent therapy
Temporary pacing (ventricular versus AV)
Intra-aortic balloon counterpulsation
Mechanical ventilation

From Gore JM, Zwernert PL: Hemodynamic monitoring of acute myocardial infarction. In Francis GS, Alpert JS (eds): *Modern Coronary Care*. Boston, Little, Brown, 1990, p 138.

Accurate determination of hemodynamics by clinical assessment can be difficult in critically ill patients. Use of a pulmonary artery catheter thus often leads to important changes in therapy. Of note, some reports have shown that complication and mortality rates may be higher in patients who undergo pulmonary artery catheterization, although such patients are often at higher risk initially. These observations emphasize the importance of patient selection, meticulous technique, and correct interpretation of the data obtained.¹²⁹

Hemodynamic Abnormalities

In 1976, Swan, Forrester, and associates measured cardiac output and wedge pressure simultaneously in a large series of patients with acute MI and identified four major hemodynamic subsets of patients (Table 52-9): (1) patients with normal systemic perfusion and without pulmonary congestion (normal cardiac output and normal wedge pressure), (2) patients with normal perfusion and pulmonary congestion (normal cardiac output and elevated wedge pressure), (3) patients with decreased perfusion but without pulmonary congestion (reduced cardiac output and normal wedge pressure), and (4) patients with decreased perfusion and pulmonary congestion (reduced cardiac output and elevated wedge pressure). This classification, which overlaps with a crude clinical classification

proposed earlier by Killip and Kimball (Table 52-9), has proved quite useful, but it should be noted that patients frequently pass from one category to another with therapy and sometimes apparently even spontaneously.

Hemodynamic Subsets

A patient's clinical status typically reflects these subsets. Hypoperfusion usually becomes evident clinically when the cardiac index falls below approximately 2.2 liters/min/m², whereas pulmonary congestion is noted when the wedge pressure exceeds approximately 18 mm Hg. However, approximately 25% of patients with cardiac indices lower than 2.2 liters/min/m² and 15% of patients with elevated pulmonary capillary wedge pressure are not recognized clinically. Discrepancies in the hemodynamic and clinical classification of patients with STEMI arise for a variety of reasons. Patients may exhibit "phase lags" as clinical pulmonary congestion develops or resolves, symptoms secondary to chronic obstructive pulmonary disease may be confused with those resulting from pulmonary congestion, or longstanding left ventricular dysfunction may mask signs of hypoperfusion because of compensatory vasoconstriction.

The hemodynamic findings shown in Tables 52-9 and 52-10 allow rational approaches to therapy. The goals of hemodynamic therapy include maintenance of ventricular performance, blood pressure support, and protection of jeopardized myocardium. Because these goals may occasionally be at cross-purposes, recognition of the hemodynamic profile, as assessed clinically or as available from hemodynamic monitoring, may be needed to design an optimal therapeutic management strategy.

Hypotension in the Prehospital Phase

Hypotension associated with bradycardia often reflects excessive vagotonia. Relative or absolute hypovolemia is often present when hypotension occurs with a normal or rapid heart rate. Marked diaphoresis, reduction of fluid intake, or vomiting during the period preceding and accompanying the onset of STEMI may all contribute to the development of hypovolemia. Even if the effective vascular volume is normal, relative hypovolemia may be present because ventricular compliance is reduced in cases of STEMI, and a left ventricular filling pressure as high as 20 mm Hg may be necessary to provide optimal preload.

MANAGEMENT. In the absence of heart failure and the presence of hypotension suspected of being due to excessive vagotonia, patients should be placed in the reverse Trendelenburg position, and in patients with sinus bradycardia and hypotension, atropine should be administered (0.3 to 0.6 mg intravenously, repeated at 3- to 10-minute intervals up to 2 mg). If these measures do not correct the hypotension, normal saline should be administered intravenously (e.g., beginning with a bolus of 100 mL, followed by 50-mL increments every 5 minutes) while monitoring for signs of heart

TABLE 52-9 Hemodynamic Classifications of Patients with Acute Myocardial Infarction

A. BASED ON CLINICAL EXAMINATION		B. BASED ON INVASIVE MONITORING	
Class	Definition	Subset	Definition
I	Rales and S ₃ absent	I	Normal hemodynamics PCWP <18, CI >2.2
II	Crackles, S ₃ gallop, elevated jugular venous pressure	II	Pulmonary congestion PCWP >18, CI >2.2
III	Frank pulmonary edema	III	Peripheral hypoperfusion PCWP <18, CI <2.2
IV	Shock	IV	Pulmonary congestion and peripheral hypoperfusion PCWP >18, CI <2.2

CI = cardiac index; PCWP = pulmonary capillary wedge pressure.

failure. Because of the poor correlation between left ventricular filling pressure and mean right atrial pressure, assessment of systemic (even central) venous pressure can be of limited value as a guide to fluid therapy. Administration of positive inotropic agents is indicated during the prehospital phase if systemic hypotension persists despite correction of hypovolemia.

The Hyperdynamic State

When infarction is not complicated by hemodynamic impairment, no therapy other than general supportive measures and treatment of arrhythmias is necessary. However, if the hemodynamic profile involves a hyperdynamic state—that is, elevation of the sinus rate, arterial pressure, and cardiac index, occurring singly or together in the presence of a normal or low left ventricular filling pressure—and if infection and other causes of tachycardia such as fever can be excluded, treatment with beta blockers is indicated. Presumably, the increased heart rate and blood pressure result from inappropriate activation of the sympathetic nervous system, possibly because of augmented release of catecholamines triggered by pain and/or anxiety.

Left Ventricular Failure

Left ventricular dysfunction is the single most important predictor of mortality following STEMI (Fig. 52-23).¹³⁰⁻¹³³ In patients with STEMI, either systolic dysfunction alone or both systolic and diastolic dysfunction can occur. Left ventricular diastolic dysfunction leads to pulmonary venous hypertension and pulmonary congestion. Clinical manifestations of left ventricular failure become more common as the extent of injury to the left ventricle increases. In addition to infarct size, other important predictors of the development of symptomatic left ventricular dysfunction include advanced age and diabetes.^{132,134} Mortality increases in association with the severity of the hemodynamic deficit.

Therapeutic Implications

Classification of patients with STEMI by hemodynamic subsets has therapeutic relevance. As already noted, patients with normal wedge pressure and hypoperfusion may benefit from infusion of fluids because the peak stroke volume value is not usually attained until left ventricular filling pressure reaches 18 to 24 mm Hg. However, a low level of left ventricular filling pressure does not necessarily imply that the left ventricular damage is slight. Such patients may be relatively hypovolemic and/or may have suffered a right ventricular infarct with or without severe left ventricular damage.

The relationship between ventricular filling pressure and cardiac index when preload is increased by infusion of fluid can provide valuable hemodynamic information in addition to that obtained from

baseline measurements. For example, the ventricular function curve rises steeply (marked increase in cardiac index, small increase in filling pressure) in patients with normal left ventricular function and hypovolemia, whereas the curve rises gradually or remains flat in patients with a combination of hypovolemia and depressed cardiac function. Invasive hemodynamic monitoring can help guide therapy in patients with severe left ventricular failure (pulmonary capillary wedge pressure >18 mm Hg and cardiac index <2.2 liters/min/m²). Although positive inotropic agents can be useful, they do not represent the initial therapy of choice for patients with STEMI. Instead, heart failure is managed most effectively first by reducing ventricular preload and then, if possible, by lowering afterload. Arrhythmias can contribute to hemodynamic compromise and should be treated promptly in patients with left ventricular failure.

Hypoxemia

In STEMI complicated by heart failure, hypoxemia caused by a combination of pulmonary vascular engorgement (and in some cases, pulmonary interstitial edema), diminished vital capacity, and in some patients, contributory respiratory depression from narcotic analgesics characteristically develops. Hypoxemia can impair the function of ischemic tissue at the margin of the infarct and thereby contribute to establishing or perpetuating the vicious cycle (see Chapter 51). The ventilation-perfusion mismatch that results in hypoxemia requires careful attention to ventilatory support. Increasing fractions of inspired oxygen (FIO₂) via facemask should be used initially, but if oxygen saturation cannot be maintained above 85% to 90% with 100% FIO₂, strong consideration should be given to endotracheal intubation and positive-pressure ventilation. The improvement in arterial oxygenation and hence myocardial oxygen supply may help restore ventricular performance. Positive end-expiratory pressure may diminish systemic venous return and reduce effective left ventricular filling pressure. This effect may require reducing the amount of positive end-expiratory pressure, normal saline infusions to maintain left ventricular filling pressure, adjustment of the rate of infusion of vasodilators such as nitroglycerin, or some combination of these factors. Because myocardial ischemia frequently occurs during the return to unsupported spontaneous breathing, weaning should be accompanied by observation for signs of ischemia and may benefit from a period of supported ventilation before extubation in patients who are not already revascularized.

Diuretics

Mild heart failure in patients with STEMI frequently responds well to diuretics such as furosemide administered intravenously in doses of 10 mg to 40 mg, repeated at 3- to 4-hour intervals if necessary. The resultant decrease in pulmonary capillary pressure reduces dyspnea, and the lowering of left ventricular wall tension that accompanies the reduction in left ventricular diastolic volume diminishes myocardial oxygen requirements and may lead to improvement in contractility and augmentation of the ejection fraction, stroke volume, and cardiac output. The reduction in elevated left ventricular filling pressure may also enhance myocardial oxygen delivery by diminishing the impedance to coronary perfusion attributable to the elevated ventricular wall tension. It may also improve arterial oxygenation by reducing pulmonary vascular congestion.

Intravenous administration of furosemide reduces pulmonary vascular congestion and pulmonary venous pressure within 15 minutes, before renal excretion of sodium and water has occurred; presumably this action results from a direct dilating effect of this drug on the systemic arterial bed. Left ventricular filling pressure should not be reduced much below 18 mm Hg, the lower range being associated with optimal left ventricular performance in patients with STEMI, because this may reduce cardiac output further and cause arterial hypotension. Excessive diuresis may also result in hypokalemia.

Afterload Reduction

Myocardial oxygen requirements depend on left ventricular wall stress, which in turn is proportional to the product of the

FIGURE 52-23 Impact of left ventricular function on survival following MI. The curvilinear relationship between the left ventricular ejection fraction (EF) in patients treated in the reperfusion era is shown. In patients with a left ventricular EF below 40%, the rate of mortality markedly increases at 6 months. (Modified from Volpi A, De Vita C, Franzosi MG, et al: Determinants of 6-month mortality in survivors of myocardial infarction after thrombolysis. Results of the GISSI-2 data base. The Ad Hoc Working Group of the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI)-2 Data Base. *Circulation* 88:416, 1993.)

peak developed left ventricular pressure, volume, and wall thickness. Intravenous vasodilator therapy should be considered in patients with STEMI complicated by (1) heart failure unresponsive to treatment with diuretics, (2) hypertension, (3) mitral regurgitation, or (4) ventricular septal defect. In these patients, treatment with vasodilator agents increases stroke volume and may reduce myocardial oxygen requirements and thereby lessen ischemia. Hemodynamic monitoring of systemic arterial and, in many cases, pulmonary capillary wedge (or at least pulmonary artery) pressure and cardiac output in patients treated with these agents is generally indicated. Improvement in cardiac performance and energetics requires three simultaneous effects: (1) reduction of left ventricular afterload, (2) avoidance of excessive systemic arterial hypotension to maintain effective coronary perfusion pressure, and (3) avoidance of excessive reduction of ventricular filling pressure with consequent diminution of cardiac output. In general, pulmonary capillary wedge pressure should be maintained at approximately 18 mm Hg and arterial pressure higher than 90/60 mm Hg in patients who were normotensive before the development of STEMI.

Vasodilator therapy is particularly useful when STEMI is complicated by mitral regurgitation or rupture of the ventricular septum. In such patients, vasodilators alone or in combination with intra-aortic balloon counterpulsation can sometimes serve as a “holding maneuver” and provide sufficient hemodynamic stabilization to permit definitive catheterization and angiographic studies, as well as to prepare the patient for early intervention. Because of the precarious state of patients with complicated infarction and the need for meticulous adjustment of dosage, therapy is best initiated with agents that can be administered intravenously and have a short duration of action, such as nitroprusside or nitroglycerin. After initial stabilization, the medication of choice is generally an ACE inhibitor, but long-acting nitrates given by mouth can also be useful.

Nitroglycerin

This drug has been shown in animal experiments to be less likely than nitroprusside to produce “coronary steal” (i.e., diversion of blood flow from the ischemic to the nonischemic zone). Therefore apart from consideration of its routine use in STEMI patients discussed earlier, it may be a particularly useful vasodilator in patients with STEMI complicated by left ventricular failure. A dosage of 10 to 15 mg/min is infused, and the dose is increased by 10 mg/min every 5 minutes until the desired effect (improvement in hemodynamics or relief of ischemic chest pain) is achieved or a decline in systolic arterial pressure to 90 mm Hg or by more than 15 mm Hg has occurred. Although both nitroglycerin and nitroprusside lower systemic arterial pressure, systemic vascular resistance, and the heart rate–systolic blood pressure product, the reduction in left ventricular filling pressure is more prominent with nitroglycerin because of its relatively greater effect than nitroprusside on venous capacitance vessels. Nevertheless, in patients with severe left ventricular failure, cardiac output often increases despite the reduction in left ventricular filling pressure produced by nitroglycerin.

Oral Vasodilators

The use of oral vasodilators for the treatment of chronic congestive heart failure is discussed in [Chapter 25](#). Patients with STEMI and persistent heart failure should receive long-term RAAS inhibition.¹ The reduced ventricular load decreases the left ventricle remodeling that occurs commonly in the period after STEMI and thereby reduces the development of heart failure and risk for death.^{135,136}

Digitalis (See Chapter 25)

Although digitalis increases the contractility and oxygen consumption of normal hearts, when heart failure is present, the diminution in heart size and wall tension frequently results in a net reduction of myocardial oxygen requirements. In animals, it fails to improve ventricular performance immediately following experimental coronary occlusion, but salutary effects are elicited when it is administered several days later. The absence of early beneficial effects may be caused by the inability of ischemic tissue to respond to digitalis or

the already maximal stimulation of contractility of the normal heart by circulating and neuronally released catecholamines.

Although the issue is still controversial, the incidence of arrhythmias can be increased by digitalis glycosides when they are given to patients in the first few hours after the onset of STEMI, particularly in the presence of hypokalemia. Undesirable peripheral systemic and coronary vasoconstriction can also result from the rapid intravenous administration of rapidly acting glycosides such as ouabain.

Administration of digitalis to patients with STEMI in the hospital phase should generally be reserved for the management of supraventricular tachyarrhythmias, such as atrial flutter and fibrillation, in the setting of poor left ventricular function and heart failure persisting despite treatment with diuretics or vasodilators. There is no indication for the use of digitalis as an inotropic agent in patients without clinical evidence of left ventricular dysfunction, and it is too weak an inotropic agent to be relied on as the principal cardiac stimulant in patients with overt pulmonary edema or cardiogenic shock.

Beta-Adrenergic Agonists

When left ventricular failure is severe, as manifested by marked a reduction in the cardiac index (<2.2 liters/min/m²), and pulmonary capillary wedge pressure is at optimal (18 to 24 mm Hg) or excessive (>24 mm Hg) levels despite therapy with diuretics, beta-adrenergic agonists are indicated.¹³⁷ Dopamine and dobutamine can be useful in patients with STEMI and reduced cardiac output, increased left ventricular filling pressure, pulmonary vascular congestion, and hypotension. Fortunately, the potentially deleterious alpha-adrenergic vasoconstrictor effects exerted by dopamine occur only at higher doses than those required to increase contractility. The vasodilating actions of dopamine on renal and splanchnic vessels and its positive inotropic effects generally improve hemodynamics and renal function. In patients with STEMI and severe left ventricular failure, this drug may be started at a dose of 3 mg/kg/min and be increased stepwise to 20 mg/kg/min to reduce pulmonary capillary wedge pressure to approximately 18 mm Hg and elevate the cardiac index to exceed 2 liters/min/m².

Dobutamine has a positive inotropic action comparable to that of dopamine but a slightly less positive chronotropic effect and less vasoconstrictor activity.¹³⁷ It can be administered at a starting dose of 2 mg/kg/min and be increased stepwise to a maximum of 30 mg/kg/min. Both dopamine and dobutamine must be given carefully and with constant monitoring of the ECG, systemic arterial pressure, and pulmonary artery or pulmonary artery occlusive pressure and, if possible, with frequent measurements of cardiac output. The dose should be reduced if significant tachycardia develops, if supraventricular or ventricular tachyarrhythmias occur, or if ST-segment deviations increase.

Norepinephrine increases myocardial oxygen consumption because of its peripheral vasoconstrictor and positive inotropic actions and thus had previously been thought best not to be used in patients with MI and shock.¹³⁷ However, a randomized trial that compared norepinephrine with dopamine showed efficacy similar to or better than that of dopamine, with fewer adverse effects.¹³⁸ Use of norepinephrine in patients with cardiogenic shock has therefore increased.

Although isoproterenol is a potent cardiac stimulant that improves ventricular performance, it should be avoided in patients with STEMI. It also causes tachycardia and augments myocardial oxygen consumption and lactate production; in addition, it reduces coronary perfusion pressure by causing systemic vasodilation, and in animals it increases the extent of experimentally induced infarction.

Other Positive Inotropic Agents

Milrinone is a noncatecholamine, nonglycoside, phosphodiesterase inhibitor with inotropic and vasodilating actions.¹³⁷ It is useful in selected patients whose heart failure persists despite treatment with diuretics, who are not hypotensive, and who are likely to benefit from both an enhancement in contractility and afterload reduction. Milrinone should be given as a loading dose of 0.5 mg/kg/min administered over a 10-minute period, followed by a maintenance infusion of

0.375 to 0.75 mg/kg/min. The loading dose may be reduced or omitted if the patient has borderline hypotension.

Cardiogenic Shock

Cardiogenic shock is the most severe clinical expression of left ventricular failure and is associated with extensive damage to the left ventricular myocardium in more than 80% of STEMI patients in whom it occurs; the remainder have a mechanical defect such as ventricular septal or papillary muscle rupture or predominant right ventricular infarction.^{130,132} This low-output state is characterized by elevated ventricular filling pressure, low cardiac output, systemic hypotension, and evidence of vital organ hypoperfusion (e.g., clouded sensorium, cool extremities, oliguria, acidosis). Patients with cardiogenic shock caused by STEMI are more likely to be older; to have a history of diabetes mellitus, previous MI, or congestive heart failure; and to have sustained an anterior infarction at the time of development of shock. In the past, cardiogenic shock was reported to occur in up to 20% of patients with STEMI, but estimates from recent large trials and observational data bases report an incidence rate in the range of 5% to 8%.^{130,132,139} When shock occurs, the prognosis remains poor and few interventions, with the exception of prompt coronary revascularization, conclusively provide benefit.¹³¹

Pathologic Findings

At autopsy, more than two thirds of patients with cardiogenic shock demonstrate multivessel coronary disease, usually including the left anterior descending coronary artery. Almost all patients with cardiogenic shock exhibit thrombotic occlusion of the artery supplying the major region of recent infarction, with loss of 40% or more of left ventricular mass.¹³⁰ Patients who die of cardiogenic shock often have “piecemeal” necrosis—that is, progressive myocardial necrosis from marginal extension of the infarct into an ischemic zone bordering on the infarction. This finding is generally associated with persistent elevation of cardiac biomarkers. Such extensions and focal lesions probably result in part from the shock state itself. Early deterioration of left ventricular function secondary to apparent extension of the infarction in some cases may result from expansion of the necrotic zone of myocardium without actual extension of the necrotic process. The hydrodynamic force that develops during ventricular systole can disrupt necrotic myocardial muscle bundles with resultant expansion and thinning of the akinetic zone of myocardium, which in turn results in deterioration of overall left ventricular function.

Other causes of cardiogenic shock in patients with STEMI include mechanical defects such as rupture of the ventricular septum, a papillary muscle, or a free wall with tamponade; right ventricular infarction; or a marked reduction in preload caused by conditions such as hypovolemia.^{130,132}

Pathophysiology

The shock state in patients with STEMI appears to be the result of a vicious cycle, as demonstrated in Figure 51-14 (see Chapter 51).

Diagnosis

Cardiogenic shock is characterized by marked and persistent (>30 minutes) hypotension with systolic arterial pressure lower than 90 mm Hg and a reduction in the cardiac index (<2.2 liters/min/m²) in the presence of elevated left ventricular filling pressure (pulmonary capillary wedge pressure >18 mm Hg). Spurious estimates of left ventricular end-diastolic pressure based on measurements of pulmonary artery wedge pressure can occur in patients with marked mitral regurgitation, in which the tall *v* wave in the left atrial (and pulmonary artery wedge) pressure tracing elevates the mean pressure above left ventricular end-diastolic pressure. Accordingly, mitral regurgitation and other mechanical lesions such as ventricular septal defect, ventricular aneurysm, and pseudoaneurysm must be excluded before the diagnosis of cardiogenic shock caused by impairment of left ventricular function can be established. Mechanical complications should be suspected in any patient with STEMI in whom circulatory collapse occurs. Immediate hemodynamic, angiographic, and

echocardiographic evaluations are necessary in patients with cardiogenic shock. It is important to exclude mechanical complications because primary therapy for such lesions usually requires immediate invasive treatment with intervening support of the circulation by intra-aortic balloon counterpulsation.

Medical Management

When the aforementioned mechanical complications are not present, cardiogenic shock is caused by impairment of left ventricular function. Inotropic and vasopressor agents may be used as pharmacologic support and should be administered at the lowest possible doses. Although dopamine or dobutamine generally improves hemodynamics in these patients, unfortunately, neither appears to improve hospital survival significantly. Similarly, vasodilators have been used in an effort to elevate cardiac output and to reduce left ventricular filling pressure, but by lowering the already markedly reduced coronary perfusion pressure, myocardial perfusion can be compromised further and accelerate the vicious cycle illustrated in Figure 51-14. Vasodilators may nonetheless be used in conjunction with intra-aortic balloon counterpulsation (see the section [Mechanical Support](#)) and inotropic agents to increase cardiac output while sustaining or elevating coronary perfusion pressure.

Patients with cardiogenic shock usually have elevated systemic vascular resistance, but occasionally resistance is normal, and in a few cases vasodilation actually predominates. When systemic vascular resistance is not elevated (i.e., <1800 dynes/cm⁵) in patients with cardiogenic shock, norepinephrine, which has both alpha- and beta-adrenergic agonist properties (in doses ranging from 2 to 10 mg/min), can increase diastolic arterial pressure, maintain coronary perfusion, and improve contractility. Alpha-adrenergic agents such as phenylephrine are contraindicated in patients with cardiogenic shock (unless systemic vascular resistance is inordinately low). Calcium-sensitizing agents, such as levosimendan, may have some beneficial effects on cardiovascular outcomes, but these medications have shown little incremental value in randomized trials.¹⁴⁰

Mechanical Support (See Chapter 29)

In patients in whom pharmacologic support is failing because of end-organ hypoperfusion, initiation of mechanical circulatory support is reasonable ([Fig. 52-24](#)), but no definitive evidence has yet shown that this strategy improves outcomes.¹⁴¹

Intra-Aortic Balloon Counterpulsation

Intra-aortic balloon counterpulsation is used for the treatment of STEMI in three groups of patients: (1) those whose conditions are hemodynamically unstable and in whom support of the circulation is required for the performance of cardiac catheterization and angiography carried out to assess lesions that are potentially correctable surgically or by angioplasty, (2) those with cardiogenic shock that is unresponsive to medical management, and rarely, (3) those with refractory ischemia that is unresponsive to other treatments or who are waiting for definitive revascularization. In experimental animals, intra-aortic balloon counterpulsation decreases preload, increases coronary blood flow, and improves cardiac performance. Unfortunately, the improvement is often only temporary in patients with cardiogenic shock. Although a response to intra-aortic balloon counterpulsation correlates with better outcomes in observational studies and small randomized trials, in the largest randomized trial conducted to date, counterpulsation alone did not improve overall survival in patients with cardiogenic shock secondary to MI ([Fig. 52-25](#)).¹⁴² Nor was a benefit observed in any clinically relevant subgroups. Nevertheless, intra-aortic balloon counterpulsation is reasonable in patients with cardiogenic shock whose condition does not stabilize with other interventions and as a bridge to recovery or more advanced therapies.¹

Percutaneous Left Ventricular Assist Devices

Temporary mechanical support with left ventricular assist devices may allow time for recovery of stunned or hibernating myocardium.¹⁴³ A percutaneous left ventricular assist device may be placed by

FIGURE 52-24 Schematic representation of examples of major categories of nonsurgical mechanical circulatory support. **A**, Intra-aortic balloon pump inserted into the descending aorta between the arch vessels and renal arteries. **B**, Impella Recover (Abiomed, Aachen, Germany). This rotational flow device is percutaneously inserted via the femoral artery and positioned across the aortic valve, with flow intake in the left ventricle and outflow in the aorta. **C**, TandemHeart (CardiacAssist, Inc., Pittsburgh). A cannula is inserted percutaneously through the right femoral vein and advanced toward the right atrium, where it is introduced by transatrial septal perforation, to establish inflow into an external rotational motor. A cannula in either femoral artery then provides the outflow. (Modified from Desai NR, Bhatt DL: Evaluating percutaneous support for cardiogenic shock: Data shock and sticker shock. *Eur Heart J* 30:2073, 2009.)

cannulation of the left femoral vein and advancement to the left atrium via transseptal puncture. Blood from the left atrium is then returned by a nonpulsatile motor into the femoral artery. This system may provide up to 5 liters/min of flow. Small randomized trials have not revealed any mortality advantage over intra-aortic balloon counterpulsation,^{130,141,143} but hemodynamic improvement is greater with the percutaneous left ventricular assist device. Another percutaneous alternative is a motorized device placed across the aortic valve that delivers continuous flow of blood from the left ventricle into the aorta and provides hemodynamic support superior to that achieved with an intra-aortic balloon pump in patients with MI.¹⁴⁴ Additionally, lactate levels have been reduced with these devices, thus suggesting improved organ perfusion, although 30-day mortality remains high.¹⁴⁵ Surgically placed left ventricular devices as a bridge to transplantation or as a destination therapy are discussed in [Chapter 29](#).

Complications

Complications of intra-aortic balloon counterpulsation include damage to or perforation of the aortic wall, ischemia distal to the site of insertion of the balloon in the femoral artery, thrombocytopenia, hemolysis, atheroemboli, infection, and mechanical failure such as rupture of the balloon, as well as complications stemming directly from the anticoagulation required. Because of the potential for vascular bleeding complications, physicians have been reluctant to use intra-aortic pumps in patients who have undergone fibrinolytic therapy. However, despite the increased bleeding risk, this modality should be considered in selected patients who are candidates for an aggressive approach to revascularization because of the poor outcome in those with shock following thrombolysis (usually associated with ineffective thrombolysis). In addition to vascular complications, percutaneous left ventricular assist devices are associated with the development of systemic inflammatory response syndrome in some patients.¹⁴⁶

Revascularization

Of the five therapies frequently used to treat patients with cardiogenic shock (vasopressors, mechanical support, fibrinolysis, PCI, and CABG), the first two are useful temporizing maneuvers. Revascularization, however, appears to improve survival.

The SHOCK (SHould we emergently revascularize Occluded Coronaries for cardiogenic shock?) study evaluated early revascularization for the treatment of patients with MI complicated by cardiogenic

shock.¹³⁰ Patients with shock caused by left ventricular failure complicating STEMI were randomly assigned to emergency revascularization ($n = 152$) accomplished by either CABG or angioplasty or to initial medical stabilization ($n = 150$). In 86% of patients in both groups, intra-aortic balloon counterpulsation was performed. The primary endpoint was all-cause mortality at 30 days; a secondary endpoint was mortality at 6 months. At 30 days the overall mortality rate was 46.7% in the revascularization group—not significantly different from the 56% mortality rate observed in the medical therapy group ($P = 0.11$). Subgroups of patients in the SHOCK study who showed benefit from the early revascularization strategy (i.e., reduced 6-month mortality) were those younger than 75 years, those with a previous MI, and those randomly assigned less than 6 hours from the onset of infarction. Long-term survival improved significantly in patients with cardiogenic shock

who underwent early revascularization ([Fig. 52-26](#)). A subsequent observational study of patients with MI complicated by shock indicated that well-selected elderly patients undergoing PCI had a 1-year survival similar to that in younger patients undergoing early revascularization.¹⁴⁷

Recommendations

We recommend individualized assessment of patients to determine their desire for aggressive care and overall candidacy for further treatment (e.g., age, mental status, comorbid conditions). Patients with shock who are potential candidates for revascularization should be revascularized, which may include revascularization of significant stenoses in non-culprit arteries, with PCI and/or CABG. In patients with STEMI and shock, in whom PCI or CABG is not suitable, fibrinolytic agents can be given unless they have a contraindication.¹ Intra-aortic balloon counterpulsation and left ventricular assist devices may be considered in patients with refractory shock whose condition does not stabilize with other therapies.

Right Ventricular Infarction

The clinical features of right ventricular infarction range from mild right ventricular dysfunction to cardiogenic shock. Characteristic electrocardiographic manifestations and hemodynamic patterns ([Fig. 52-27](#)) have been observed in patients with clinically significant right ventricular infarction, which accompanies approximately a third of inferior left ventricular infarctions. Right-sided heart filling pressures (central venous, right atrial, and right ventricular end-diastolic) are elevated, whereas left ventricular filling pressure is normal or only slightly raised; right ventricular systolic and pulse pressures are decreased, and cardiac output is often markedly depressed.

Diagnosis

Many patients with the combination of a normal left ventricular filling pressure and depressed cardiac index have right ventricular infarcts (with accompanying inferior left ventricular infarcts). The hemodynamic picture may superficially resemble that seen in patients with pericardial disease ([see Chapter 71](#)) and includes elevated right ventricular filling pressure; a steep, right atrial y descent; and an early diastolic drop and plateau (resembling the square root sign) in the right ventricular pressure tracing. Moreover, patients with right ventricular infarction may display the Kussmaul sign (an increase in

FIGURE 52-25 Primary result of a randomized trial of routine insertion of an intra-aortic balloon pump (IABP) versus standard care in patients with acute MI and cardiogenic shock. **A**, In this randomized trial of 600 patients, the primary endpoint of death from any cause did not differ between the randomized treatment groups. **B**, There was no convincing benefit of the routine use of IABP for shock in any of the major subgroups examined. LBBB = left bundle branch block. (From Thiele H, Zeymer U, Neumann FJ, et al: Intraaortic balloon support for myocardial infarction with cardiogenic shock. *N Engl J Med* 367:1287, 2012.)

jugular venous pressure with inspiration) and pulsus paradoxus (a fall in systolic pressure >10 mm Hg with inspiration) (Fig. 52-27). In fact, the Kussmaul sign in the setting of inferior STEMI is highly predictive of right ventricular involvement.

The ECG can provide the first clue to right ventricular involvement in patients with inferior STEMI (Fig. 52-27). Most patients with right ventricular infarction have ST-segment elevation in lead V₄R (right

precordial lead in the V₄ position).¹ Transient elevation of the ST segment in any of the right precordial leads can occur with right ventricular MI, and the presence of ST-segment elevation of 0.1 mV or greater in any one or a combination of leads V₄R, V₅R, and V₆R in patients with the clinical picture of acute MI points to the diagnosis of right ventricular MI. In addition to noting the presence or absence of convex upward ST elevation in V₄R, clinicians should determine

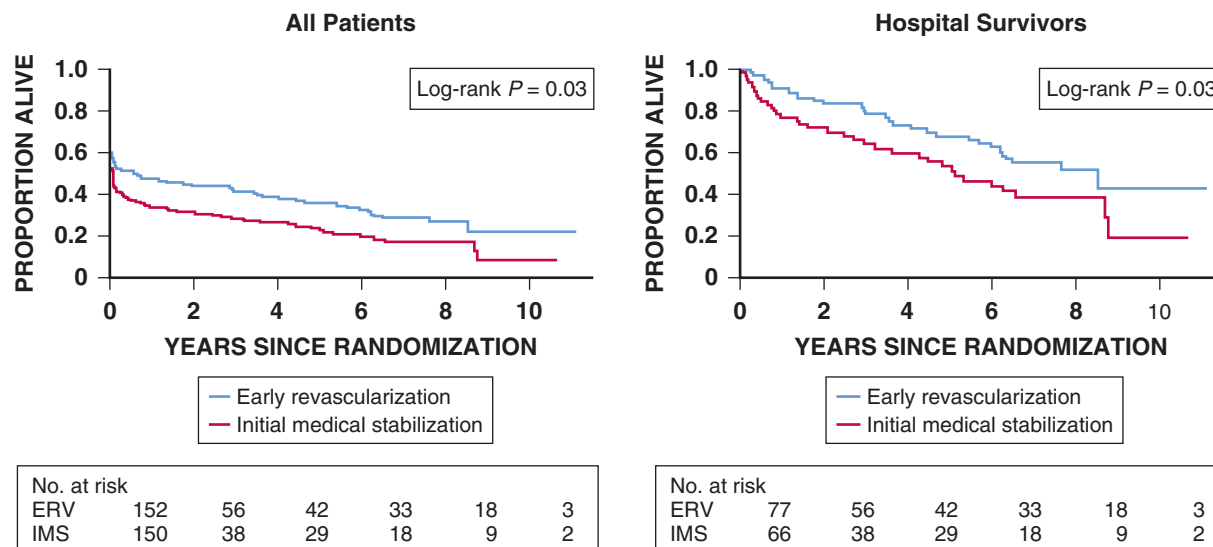

FIGURE 52-26 Impact of revascularization in patients in the SHOCK trial. Among all patients, survival rates in the early revascularization (ERV) and initial medical stabilization (IMS) groups, respectively, were 41.4% and 28.3% at 3 years and 32.8% and 19.6% at 6 years. Among hospital survivors, survival rates in the ERV and IMS groups, respectively, were 78.8% and 64.3% at 3 years and 62.4% and 44.4% at 6 years. (From Hochman JS, Sleeper LA, Webb JG, et al: Early revascularization and long-term survival in cardiogenic shock complicating acute myocardial infarction. *JAMA* 295:2511, 2006.)

FIGURE 52-27 Right ventricular infarction: diagnosis, clinical features, and management. **A**, Placement of right-sided leads for electrocardiographic evaluation of right ventricular infarction. **B**, ST elevation is seen in the right-sided ECG leads, with variation in the repolarization pattern depending on the infarct artery and the location of the occlusion. **C**, Patients with hemodynamically significant right ventricular infarction have shock but clear lungs and elevated jugular venous pressure. Management is directed at maintaining adequate right ventricular preload and lowering pulmonary artery pressure to unload the right ventricle. Inotropic therapy may be necessary in some cases. Echo = echocardiogram; JVP = jugular venous pressure; RA = right atrial; RV = right ventricular. (Modified from Wellens HJ: The value of the right precordial leads of the electrocardiogram. *N Engl J Med* 340:381, 1999; and Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation* 2004;110(9):e82.)

whether the T wave is positive or negative—such distinctions help distinguish proximal versus distal occlusion of the right coronary artery versus occlusion of the left circumflex artery (Fig. 52-27). Elevation of the ST segments in leads V₁ through V₄ caused by right ventricular infarction can be confused with elevation caused by anteroseptal infarction. Although the elevated ST segments are oriented anteriorly in both cases, the frontal plane can provide important clues—the ST segments are oriented to the right with right ventricular infarction (e.g., +120 degrees), whereas they are oriented to the left with anteroseptal infarction (e.g., -30 degrees).

Noninvasive Assessment

Echocardiography helps in the differential diagnosis because in patients with right ventricular infarction, in contrast to pericardial tamponade, little or no pericardial fluid accumulates. The echocardiogram shows abnormal wall motion of the right ventricle, as well as right ventricular dilation and depression of the right ventricular ejection fraction.¹⁴⁸ MRI can also aid in recognition of right ventricular infarction.¹⁴⁹ Impaired right ventricular function delineated by either modality has been associated with increased mortality after MI.¹⁵⁰ Additionally, shock from isolated right ventricular dysfunction carries almost as high a mortality risk as left ventricular shock does; serial studies have shown, however, that some degree of ventricular recovery is more common with right ventricular infarction than with left ventricular infarction.¹³⁰

Treatment

Because of their ability to reduce preload, medications routinely prescribed for left ventricular infarction may produce profound hypotension in patients with right ventricular infarction. Specifically, nitrates and diuretics should be avoided. In patients with hypotension caused by right ventricular MI, hemodynamics can be improved by a combination of expansion of plasma volume to augment right ventricular preload and cardiac output and, when left ventricular failure is present, arterial vasodilators.¹ If hypotension has not responded to

brisk administration of 1 or more liters of fluid, however, consideration should be given to hemodynamic monitoring with a pulmonary artery catheter because further volume infusion may be of little use and could produce pulmonary congestion. Arterial vasodilators reduce the impedance to left ventricular outflow and, in turn, left ventricular diastolic, left atrial, and pulmonary (arterial) pressure—thereby lowering impedance to right ventricular outflow and enhancing right ventricular output.

In patients requiring pacing, ventricular pacing may fail to increase cardiac output, and AV sequential pacing may be needed. Right ventricular infarction is common in patients with inferior left ventricular infarction. Therefore otherwise unexplained systemic arterial hypotension with diminished cardiac output or marked hypotension in response to small doses of nitroglycerin in patients with inferior infarction should lead to prompt consideration of this diagnosis. Patients requiring pacing should undergo atrial or AV sequential pacing. Successful reperfusion of the right coronary artery significantly improves right ventricular mechanical function and lowers in-hospital mortality in patients with right ventricular infarction. Replacement of the tricuspid valve and repair of the valve with annuloplasty rings have been performed for the treatment of severe tricuspid regurgitation caused by right ventricular infarction.

Mechanical Causes of Heart Failure

The most dramatic complications of STEMI involve tearing or rupture of acutely infarcted tissue (see Fig. 52-33). The clinical characteristics of these lesions vary considerably and depend on the site of rupture, which may involve the free wall of either ventricle, the interventricular septum, or the papillary muscles. The overall incidence of these complications, although difficult to assess because clinical and autopsy series differ considerably, appears to be decreasing with the increasing use of reperfusion therapy.^{151,152} Table 52-11 shows the comparative clinical profile of these complications, as gathered from different studies.

TABLE 52-11 Characteristics of Ventricular Septal Rupture, Rupture of the Ventricular Free Wall, and Papillary Muscle Rupture

CHARACTERISTIC	VENTRICULAR SEPTAL RUPTURE	RUPTURE OF THE VENTRICULAR FREE WALL	PAPILLARY MUSCLE RUPTURE
Incidence	1-3% without reperfusion therapy, 0.2-0.34% with fibrinolytic therapy, 3.9% in patients with cardiogenic shock	0.8-6.2%; fibrinolytic therapy does not reduce risk; primary PTCA seems to reduce risk	≈1% (the posteromedial more frequent than the anterolateral papillary muscle)
Time course	Bimodal peak; within 24 hr and 3-5 days; range, 1-14 days	Bimodal peak; within 24 hr and 3-5 days; range, 1-14 days	Bimodal peak; within 24 hr and 3-5 days; range, 1-14 days
Clinical manifestations	Chest pain, shortness of breath, hypotension	Anginal, pleuritic, or pericardial chest pain; syncope; hypotension; arrhythmia; nausea; restlessness; hypotension; sudden death	Abrupt onset of shortness of breath and pulmonary edema; hypotension
Physical findings	Harsh holosystolic murmur, thrill (+), S ₃ , accentuated second heart sound, pulmonary edema, RV and LV failure, cardiogenic shock	Jugular venous distention (29% of patients), pulsus paradoxus (47%), electromechanical dissociation, cardiogenic shock	A soft murmur in some cases, no thrill, variable signs of RV overload, severe pulmonary edema, cardiogenic shock
Echocardiographic findings	Ventricular septal rupture, left-to-right shunt on color flow Doppler echocardiography through the ventricular septum, pattern of RV overload	>5 mm pericardial effusion not visualized in all cases; layered, high-acoustic echoes within the pericardium (blood clot); direct visualization of tear; signs of tamponade	Hypercontractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe mitral regurgitation on color flow Doppler echocardiography
Right-heart catheterization	Increase in oxygen saturation from the RA to RV, large v waves	Ventriculography insensitive, classic signs of tamponade not always present (equalization of diastolic pressures in the cardiac chambers)	No increase in oxygen saturation from the RA to RV, large v waves,* very high pulmonary capillary wedge pressure

*Large v waves are from the pulmonary capillary wedge pressure.

LV = left ventricle/left ventricular; PTCA = percutaneous transluminal coronary angioplasty; RA = right atrium; RV = right ventricle/right ventricular.

(www.acc.org/clinical/guidelines/stemi/index.pdf). Accessed April 19, 2006.

Free Wall Rupture

The clinical course of rupture varies from catastrophic, with an acute tear leading to tamponade and immediate death, to subacute, with nausea, hypotension, and pericardial discomfort being the major clinical clues to its presence (Table 52-11). The tear is usually preceded by a large infarct with subsequent expansion, sometimes with a dissecting hematoma, and occurs near the junction of the infarct and normal muscle. Rupture is more common in the left ventricle (specifically, the anterior or lateral wall) than in the right ventricle and seldom occurs in the atria. Other features associated with rupture include reperfusion with a fibrinolytic agent versus PCI, older age, female sex, hypertension, the absence of collateral circulation, and a first MI.¹⁵² Survival depends on recognition of this complication, on hemodynamic stabilization of the patient—usually with inotropic agents and/or an intra-aortic balloon pump—and most importantly, on prompt surgical repair.¹

Pseudoaneurysm

Incomplete rupture of the heart may occur when organizing thrombus and hematoma, together with pericardium, seal a rupture of the left ventricle and thus prevent the development of hemopericardium (Fig. 52-28). With time, this area of organized thrombus and pericardium can become a pseudoaneurysm (false aneurysm) that maintains communication with the cavity of the left ventricle. In contrast to true aneurysms, which always contain some myocardial elements in their walls, the walls of pseudoaneurysms are composed of organized hematoma and pericardium and lack any elements of the original myocardial wall. Pseudoaneurysms can become quite large, even equaling the true ventricular cavity in size, and they communicate with the left ventricular cavity through a narrow neck. Frequently, pseudoaneurysms contain significant quantities of old and recent thrombi, the superficial portions of which can cause arterial emboli. Pseudoaneurysms can drain off a portion of each ventricular stroke volume, exactly as true aneurysms do. The diagnosis of pseudoaneurysm can usually be made by echocardiography and contrast-enhanced angiography,¹⁵⁰ although differentiation between a true aneurysm and a pseudoaneurysm can sometimes be difficult with any imaging technique.

Diagnosis

Myocardial free wall rupture is usually accompanied by sudden profound shock, often rapidly leading to pulseless electrical activity caused by pericardial tamponade. Immediate pericardiocentesis can confirm the diagnosis and relieve the pericardial tamponade, at least momentarily. If the patient's condition is relatively stable, echocardiography may help in establishing the diagnosis of tamponade.¹⁵⁰

Treatment

In patients with critically compromised hemodynamics, establishment of the diagnosis should be followed immediately by surgical resection of the necrotic and ruptured myocardium with primary reconstruction. When the rupture is subacute and a pseudoaneurysm is suspected or present, prompt elective surgery is indicated because rupture of the pseudoaneurysm can occur relatively frequently.¹⁵³

Rupture of the Interventricular Septum

As in rupture of the free wall of the ventricle, transmural infarction underlies rupture of the ventricular septum. The perforation can range in length from one to several centimeters (Fig. 52-29). It can be a direct through-and-through opening or more irregular and serpiginous. Rupture of the septum with an anterior infarction tends to be apical in location, whereas inferior infarctions are associated with perforation of the basal septum and have a worse prognosis than do those in an anterior location.

Clinical features associated with increased risk for rupture of the interventricular septum include lack of development of a collateral network, advanced age, female sex, and chronic kidney disease (Table 52-12). Because previous ischemia induces myocardial preconditioning, thereby decreasing the likelihood of transmural myocardial necrosis and septal rupture, patients with evidence of hypertension, diabetes mellitus, chronic angina, or previous MI are less likely to experience rupture.¹³²

A ruptured interventricular septum is characterized by the appearance of a new harsh, loud holosystolic murmur that is heard best at the lower left sternal border and is usually accompanied by a thrill. Biventricular failure generally ensues within hours to days. The defect can also be recognized by echocardiography with color flow Doppler

TABLE 52-12 Cardiac Arrhythmias and Their Management During Acute Myocardial Infarction

CATEGORY	ARRHYTHMIA	OBJECTIVE OF TREATMENT	THERAPEUTIC OPTIONS
1. Electrical instability	Ventricular premature beats	Correction of electrolyte deficits and increased sympathetic tone	Potassium and magnesium solutions, beta blocker
	Ventricular tachycardia	Prophylaxis against ventricular fibrillation, restoration of hemodynamic stability	Antiarrhythmic agents, beta blocker; cardioversion/defibrillation
	Ventricular fibrillation	Urgent reversion to sinus rhythm	Defibrillation; amiodarone, lidocaine
	Accelerated idioventricular rhythm	Observation unless hemodynamic function is compromised	Increase sinus rate (atropine, atrial pacing); antiarrhythmic agents
	Nonparoxysmal AV junctional tachycardia	Search for precipitating cause (e.g., digitalis intoxication); suppress arrhythmia only if hemodynamic function is compromised	Atrial overdrive pacing; antiarrhythmic agents; cardioversion relatively contraindicated if digitalis intoxication present
2. Pump failure/excessive sympathetic stimulation	Sinus tachycardia	Reduce heart rate to diminish myocardial oxygen demands	Antipyretics; analgesics; consider beta-blocking agent unless congestive heart failure present
	Atrial fibrillation and/or atrial flutter	Reduce ventricular rate; restore sinus rhythm	Verapamil, digitalis glycosides; amiodarone; treat heart failure; cardioversion
	Paroxysmal supraventricular tachycardia	Reduce ventricular rate; restore sinus rhythm	Vagal maneuvers; verapamil, cardiac glycosides, beta-adrenergic blocking agents; cardioversion
3. Bradyarrhythmias and conduction disturbances	Sinus bradycardia	Acceleration of the heart rate only if hemodynamic function is compromised	Atropine; atrial pacing
	Junctional escape rhythm	Acceleration of the sinus rate only if loss of atrial “kick” causes hemodynamic compromise	Atropine; atrial pacing
	AV block and intraventricular block		Insertion of a pacemaker

Modified from Antman EM, Rutherford JD (eds): *Coronary Care Medicine: A Practical Approach*. Boston, Martinus Nijhoff, 1986, p 78.

imaging (Fig. 52-30) or by insertion of a pulmonary artery balloon catheter to document the left-to-right shunt. Rupture of the interventricular septum after STEMI confers high 30-day mortality.¹⁵² The likelihood of survival depends on the degree of impairment of ventricular function and the size of the defect, but because the rupture site can expand, prompt surgical repair is necessary even in hemodynamically stable patients.^{1,154}

Rupture of a Papillary Muscle

Partial or total rupture of a papillary muscle is a rare but often fatal complication of transmural MI (see Fig. 52-29).¹⁵⁵ Complete transection of a left ventricular papillary muscle is incompatible with life because the sudden massive mitral regurgitation that develops cannot be tolerated. Rupture of a portion of a papillary muscle, usually the tip or head of the muscle, that results in severe, although

FIGURE 52-30 Echocardiography of two ventricular septal defects (VSDs) that developed after STEMI. A close-up of the ventricular septum in an apical four-chamber view demonstrates turbulent systolic color flow Doppler across a VSD and continuous-wave Doppler demonstrates systolic flow across a VSD (**left**). (From Kamran M, Attari M, Webber G: *Images in cardiovascular medicine*. Ventricular septal defect complicating an acute myocardial infarction. *Circulation* 112:e337, 2005.) A subcostal view demonstrates color flow Doppler across a VSD (**right**). (From Brigham and Women's Hospital, 2013.) LV = left ventricle; RV = right ventricle.

FIGURE 52-31 Surgical specimen showing a papillary muscle (**top left**), chordae, and anterior mitral leaflet (**bottom right**) from a patient who had a partial rupture of the papillary muscle and underwent mitral valve replacement for severe mitral regurgitation after STEMI. (Courtesy Dr. John Byrne, Brigham and Women's Hospital, Boston.)

not necessarily overwhelming mitral regurgitation is much more frequent and is not immediately fatal (**Fig. 52-31**). Inferior wall infarction can lead to rupture of the posteromedial papillary muscle, which because of its singular blood supply, occurs more commonly than does rupture of the anterolateral muscle, a consequence of anterolateral MI. Unlike rupture of the ventricular septum, which occurs with large infarcts, papillary muscle rupture occurs with a relatively small infarction in approximately half of cases. These patients can sometimes have a modest extent of CAD as well. Rupture of a right ventricular papillary muscle is unusual but can cause massive tricuspid regurgitation and right ventricular failure. In a small number of patients, rupture of more than one cardiac structure is noted clinically or at postmortem examination; all possible combinations of rupture of the left ventricular free wall, the interventricular septum, and the papillary muscles can occur.

As with patients who have a ruptured ventricular septal defect, those with papillary muscle rupture manifest a new holosystolic murmur and have increasingly severe heart failure.¹⁵⁵ In both conditions the murmur may become softer or disappear as arterial pressure falls. Mitral regurgitation secondary to partial or complete rupture of a papillary muscle can be recognized promptly with echocardiography. Color flow Doppler imaging is particularly helpful in distinguishing acute mitral regurgitation from a ventricular septal defect in the setting of STEMI (**Table 52-11**).^{1,154} An echocardiogram should therefore be obtained immediately for any patient in whom the diagnosis is suspected because hemodynamic deterioration can ensue rapidly. Echocardiography also often permits differentiation of papillary muscle rupture from other, generally less severe forms of mitral regurgitation that occur with STEMI.

Differentiation Between Ventricular Septal Rupture and Mitral Regurgitation

Distinguishing on clinical grounds between acute mitral regurgitation and rupture of the ventricular septum in patients with STEMI in whom a loud systolic murmur suddenly develops may be difficult.¹⁵⁵ Such differentiation can be made most readily by color flow Doppler echocardiography. In addition, right-heart catheterization with a balloon-tipped catheter can readily distinguish between these two complications. Patients with ventricular septal rupture demonstrate a “step-up” in oxygen saturation in blood samples from the right ventricle and pulmonary artery as compared with those from the right atrium. Patients with acute mitral regurgitation lack this step-up; they may demonstrate tall *c-v* waves in both the pulmonary capillary and pulmonary arterial pressure tracings.

Management

Invasive monitoring is generally indicated on recognition of a major mechanical complication of STEMI. Right and left ventricular filling pressures (right atrial pressure and pulmonary capillary wedge pressure) guide fluid administration or the use of diuretics, whereas measurements of cardiac output and mean arterial pressure permit calculation of systemic vascular resistance to direct vasodilator therapy. For acute mitral regurgitation and ventricular septal defects, unless systolic pressure is below 90 mm Hg, this therapy, which generally involves nitroglycerin or nitroprusside, should be instituted as soon as possible once hemodynamic monitoring is available. Inotropes may also be needed to support adequate cardiac output. These interventions may be critically important for stabilizing the patient's condition in preparation for further diagnostic studies and

repair. If pharmacologic therapy is not tolerated or if it fails to achieve hemodynamic stability, intra-aortic balloon counterpulsation should be instituted rapidly. Intra-aortic balloon counterpulsation should be considered for most patients with acute mechanical complications of STEMI.

Operative intervention is most successful in patients with STEMI and circulatory collapse when a surgically correctable mechanical lesion such as a ventricular septal defect or ruptured papillary muscle can be identified and addressed. In most cases, surgery should not be delayed in patients with a correctable lesion who agree to an aggressive management strategy and require pharmacologic and/or mechanical (counterpulsation) support.¹ In such patients a serious complication frequently develops—infection, adult respiratory distress syndrome, extension of the infarct, or renal failure—if surgery is delayed. Surgical survival is predicted by early surgery, short duration of shock, and mild degrees of right and left ventricular impairment.^{152,156} In a subset of patients whose hemodynamic status remains stable, the operation may be postponed for 2 to 4 weeks to allow some healing of the infarct. Such decisions regarding the optimal timing of surgery are complicated and require integration of multiple aspects of the clinical course, as well as the anatomy of the mechanical complication, by a multidisciplinary team. Surgical repair involves correction of mitral regurgitation, insertion of a prosthetic mitral valve, or closure of a ventricular septal defect, usually accompanied by coronary revascularization (Figs. 52-32 and 52-33).

Catheter-based options for repair of ventricular septal defects may be appropriate in patients who are not candidates for early definitive surgical correction.^{146,157} Because complete closure of the defect, however, requires time for the device to thrombose and endothelialize, in most patients with hemodynamically significant mechanical complications, surgical management is the best established management option.¹

FIGURE 52-32 Surgical management of mitral regurgitation caused by a ruptured papillary muscle. **A**, An acute papillary muscle rupture results in severe mitral regurgitation as a result of leaflet and commissural prolapse. Mitral valve replacement is usually necessary. **B**, Mitral débridement with retention of the unruptured commissural and leaflet segment is performed to preserve partial continuity of the annular papillary muscle. **C**, Mitral valve replacement is then performed. **D**, Occasionally, mitral valve repair can be performed by transfer of a papillary head to a nonruptured segment. (Courtesy Dr. David Adams, Mt. Sinai Hospital, New York.)

ARRHYTHMIAS (See also Chapters 37 Through 39)

Arrhythmias that can complicate the course of patients with STEMI, as well as their prevention and treatment in this setting, are discussed here and summarized in Table 52-12. Many serious arrhythmias develop before hospitalization, even before the patient is monitored. Some abnormality in cardiac rhythm also occurs in many patients with STEMI treated in the hospital. These arrhythmias can include both tachycardic and bradycardic episodes, both of which have the ability to provoke hemodynamic consequences.

Hemodynamic Consequences

Patients with significant left ventricular dysfunction have a relatively fixed stroke volume and depend on changes in the heart rate to alter cardiac output. However, the range of heart rate with maximal cardiac output is narrow: either faster or slower rates can cause reductions in output. Thus all forms of tachycardia and bradycardia can depress cardiac output in patients with STEMI. Although optimal cardiac output may require a rate higher than 100 beats/min, because heart rate is one of the major determinants of myocardial oxygen consumption, more rapid heart rates elevate myocardial energy needs to levels that can adversely affect ischemic myocardium. In patients with STEMI, therefore, the optimal rate is usually lower—in the range of 60 to 80 beats/min.

A second factor to consider in assessing the hemodynamic consequences of a particular arrhythmia is loss of the atrial contribution to ventricular preload. Studies of patients without STEMI have demonstrated that loss of atrial transport decreases left ventricular output by 15% to 20%. In patients with reduced diastolic left ventricular compliance of any cause (including STEMI), however, atrial systole is of greater importance for left ventricular filling. In patients with STEMI, atrial systole boosts end-diastolic volume by approximately 15%, end-diastolic pressure by 30%, and stroke volume by 35%.

Ventricular Arrhythmias (See Chapters 37 and 39)

Ventricular Premature Depolarizations

Before the widespread use of reperfusion therapy, aspirin, beta-blocking agents, and intravenous nitrates for the management of STEMI, frequent ventricular premature complexes (VPCs) (more than

FIGURE 52-33 Repair of an ischemic ventricular septal defect. The infarct typically involves a free wall and septum. Repair of the defect is performed through an incision in the ventricular wall infarct. The septal defect is closed with a prosthetic patch, and a second patch is used to close the incision in the free wall. (Courtesy Dr. David Adams, Mt. Sinai Hospital, New York.)

five per minute), VPCs with a multiform configuration, early coupling (the “R-on-T” phenomenon), and repetitive patterns in the form of couplets or salvos were thought to presage VF. It is now clear, however, that as many patients in whom fibrillation does not develop as those in whom it does have such “warning arrhythmias.” Several reports have shown that primary VF (see later) occurs without antecedent warning arrhythmias and may even develop despite suppression of warning arrhythmias. Both primary VF and VPCs, especially R-on-T beats, occur during the early phase of STEMI, when considerable heterogeneity in electrical activity is present. Although R-on-T beats expose this heterogeneity and can precipitate VF in a small minority of patients, the ubiquitous nature of VPCs in patients with STEMI and the extremely infrequent nature of VF in the current era of STEMI management produce unacceptably low sensitivity and specificity of the electrocardiographic patterns observed on monitoring systems for identifying patients at risk for VF.

Management

The incidence of VF in patients with STEMI seen in CCUs over the past three decades appears to have declined. The previous practice of prophylactic suppression of ventricular premature beats with antiarrhythmic drugs is not indicated and may actually increase the risk for fatal bradycardic and asystolic events.¹ We therefore pursue a conservative course when VPCs are observed in patients with STEMI and do not routinely prescribe antiarrhythmic drugs, other than beta blockers, but instead determine whether recurrent ischemia or electrolyte or metabolic disturbances are present.¹ When VPCs accompany sinus tachycardia at the inception of an infarction, augmented sympathoadrenal stimulation often contributes and can be treated by beta-adrenergic blockade. In fact, early administration of an intravenous beta blocker effectively reduces the incidence of VF in cases of evolving MI.¹⁵⁸

Accelerated Idioventricular Rhythm

An accelerated idioventricular rhythm typically occurs during the first 2 days, with about equal frequency in anterior and inferior infarctions. Most episodes are of short duration. Accelerated idioventricular rhythm is often observed shortly after successful reperfusion has been established with fibrinolytic therapy. However, the frequent occurrence of this rhythm in patients without reperfusion limits its reliability as a marker of the restoration of patency of the infarct-related coronary artery and may have different implications following primary PCI.¹⁵⁹ In contrast to rapid VT, accelerated idioventricular rhythm is thought not to affect prognosis, and we do not routinely treat accelerated idioventricular rhythms.

Ventricular Tachycardia and Ventricular Fibrillation

A leading hypothesis for a major mechanism of ventricular arrhythmias in the acute phase of coronary occlusion is reentry caused by inhomogeneity of the electrical characteristics of ischemic myocardium.¹⁶⁰ The cellular electrophysiologic mechanisms for reperfusion arrhythmias appear to include washout of various ions such as lactate and potassium and toxic metabolic substances that have accumulated in the ischemic zone. VT and/or VF occurring late in the course of STEMI is more common in patients with transmural infarction and left ventricular dysfunction and is more frequently associated with hemodynamic deterioration.

Prophylaxis

Because hypokalemia can increase the risk for development of VT, low serum potassium levels should be identified quickly after admission for STEMI and should be treated promptly.¹⁶¹ Despite the lack of a consistent relationship between hypomagnesemia and ventricular arrhythmias, magnesium deficits may still be linked to risk because patients with STEMI have reduced intracellular magnesium levels not adequately reflected by serum measurements. As noted earlier, magnesium should be repleted to achieve a serum level of 2 mEq/liter. Early beta blocker use has reduced VF and can be instituted in patients without contraindication. Lidocaine prophylaxis to prevent primary VF is no longer advised.¹

Management

Treatment of unstable VT or VF consists of electrical cardioversion implemented as rapidly as possible. Successful interruption of unstable ventricular arrhythmias or prevention of refractory recurrent episodes can also be facilitated by the intravenous administration of amiodarone. We do not usually administer bicarbonate injections to correct acidosis because of the high osmotic load that they impose and because hyperventilation of the patient is probably a more suitable means of clearing the acidosis. After reversion to sinus rhythm, every effort should be made to correct any underlying abnormalities such as hypoxia, hypotension, acid-base or electrolyte disturbances, and digitalis excess. Urgent attempts at revascularization are warranted if ventricular arrhythmias are ongoing and caused by ischemia. The use of extended antiarrhythmic drug therapy, such as amiodarone or lidocaine, is discussed in [Chapter 37](#). In patients with sustained VT or VF successfully treated at a time after successful reperfusion, we generally continue antiarrhythmic drug therapy, most often amiodarone, until a defibrillator is placed.

Failure of electrical cardioversion to restore an effective cardiac rhythm is almost always caused by rapidly recurrent VT or VF, by electromechanical dissociation, or rarely, by electrical asystole. When synchronous cardiac electrical activity is restored by counter-shock but contraction is ineffective (i.e., pulseless electrical activity), the underlying cause is usually extensive myocardial ischemia or necrosis or rupture of the ventricular free wall or septum.

The highest rates of successful treatment of VT/VF occur in the intensive care setting. When ventricular arrhythmias occur outside an intensive care unit, resuscitative efforts are much less likely to be successful, primarily because the time interval between onset of the episode and institution of definitive therapy tends to be prolonged.

Prognosis

Among patients who underwent fibrinolytic therapy in the GUSTO-I (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) study, approximately 10% experienced VT/VF. In the APEX-AMI (Assessment of Pexelizumab in Acute Myocardial Infarction) study, which included patients treated with primary PCI, sustained VT/VF developed in 5.7%. Clinical outcomes were worse in patients with VT/VF than in those without VT/VF. Additionally, mortality rates were worse in those with early versus late VT/VF; specifically, when compared with patients without VT/VF, the risk for mortality at 90 days increased twofold in patients with both early and late VT/VF, respectively.¹⁵⁸ In patients in whom sustained VT/VF develops later in the course after STEMI (e.g., after more than 48 hours) without evidence of a reversible cause, implantable cardioverter-defibrillator (ICD) therapy for secondary prevention should be considered before discharge.¹ This situation differs from that in patients with VT/VF *before* reperfusion therapy, in whom antiarrhythmic therapy other than a beta blocker is not indicated. Indications for insertion of an ICD for *primary* prevention in patients with a reduced left ventricular ejection fraction after STEMI are discussed later in this chapter.

Bradyarrhythmias (See Chapters 36 and 37)

Sinus Bradycardia

Sinus bradycardia occurs commonly during the early phases of STEMI, particularly in patients with inferior and posterior infarctions. On the basis of data obtained from experimental infarction and from some clinical observations, the increased vagal tone that produces sinus bradycardia during the early phase of STEMI may actually be beneficial, perhaps because it reduces myocardial oxygen demand. Thus the acute mortality rate in patients with sinus bradycardia appears to be similar to that in those without this arrhythmia.¹

Management

Isolated sinus bradycardia, unaccompanied by hypotension or ventricular ectopy, should be observed rather than treated initially. In the first 4 to 6 hours after infarction, if the sinus rate is extremely low (<40 to 50 beats/min) and associated with hypotension, intravenous

atropine in doses of 0.3 to 0.6 mg every 3 to 10 minutes (with a total dose not exceeding 3 mg) can be administered to bring the heart rate up to approximately 60 beats/min.

Atrioventricular and Intraventricular Block

Ischemic injury can produce conduction block at any level of the AV or intraventricular conduction system. Such blocks can occur in the AV node and the bundle of His and produce various grades of AV block, in either main bundle branch and produce right or left bundle branch block, and in the anterior and posterior divisions of the left bundle and produce left anterior or left posterior (fascicular) divisional blocks. Conduction disturbances can, of course, occur in various combinations. The clinical features of proximal and distal AV conduction disturbances in patients with STEMI are summarized in [Table 52-13](#).

First-Degree Atrioventricular Block

A first-degree AV block does not generally require specific treatment. Beta blockers and calcium antagonists (other than dihydropyridines) prolong AV conduction and may be responsible for first-degree AV block as well, but discontinuation of the use of these drugs in the setting of STEMI could increase ischemia and ischemic injury. Therefore we do not decrease the dosage of these drugs unless the PR interval is greater than 0.24 second. Use of these agents should be stopped only if a higher-degree block or hemodynamic impairment occurs. If the block is a manifestation of excessive vagotonia and is associated with sinus bradycardia and hypotension, administration of atropine, as already outlined, may be helpful. Continued

electrocardiographic monitoring is important in such patients in view of the possibility of progression to higher degrees of block.

Second-Degree Atrioventricular Block

First-degree and type I second-degree AV blocks do not appear to affect survival, are most commonly associated with occlusion of the right coronary artery, and are caused by ischemia of the AV node ([Table 52-13](#)). Specific therapy is not required in patients with second-degree type I AV block when the ventricular rate exceeds 50 beats/min and PVCs, heart failure, and bundle branch block are absent. If these complications develop, however, or if the heart rate falls below approximately 50 beats/min and the patient is symptomatic, immediate treatment with atropine (0.3 to 0.6 mg) is indicated; temporary pacing systems are almost never needed in the management of this arrhythmia.

Type II second-degree AV block in the setting of inferior/posterior STEMI is usually temporary and is manifested as a narrow-complex/junctional escape rhythm. These arrhythmias can typically be managed conservatively. With anterior/lateral STEMI, a type II second-degree AV block usually originates from a lesion in the conduction system below the bundle of His ([Table 52-13](#)). Because of its potential for progression to complete heart block, type II second-degree AV block in this setting should be treated with a temporary external or transvenous demand pacemaker.¹

Complete (Third-Degree) Atrioventricular Block

Complete AV block can occur in patients with either inferior or anterior infarction, although it is more common in the inferior than in the anterior location. Complete heart block in patients with inferior

TABLE 52-13 Atrioventricular Conduction Disturbances in Acute Myocardial Infarction

LOCATION OF AV CONDUCTION DISTURBANCE		
	Proximal	Distal
Site of block	Intranodal	Infranodal
Site of infarction	Inferoposterior	Anteroseptal
Compromised arterial supply	RCA (90%), LCX (10%)	Septal perforators of the LAD
Pathogenesis	Ischemia, necrosis, hydropic cell swelling, excessive parasympathetic activity	Ischemia, necrosis, hydropic cell swelling
Predominant type of AV nodal block	First-degree (PR >200 msec) Mobitz type I second-degree	Mobitz type II second-degree Third-degree
Common premonitory features of third-degree AV block	First- or second-degree AV block Mobitz I pattern	Intraventricular conduction block Mobitz II pattern
Features of escape rhythm following third-degree block		
Location	Proximal conduction system (His bundle)	Distal conduction system (bundle branches)
QRS width	<0.12/sec*	>0.12/sec
Rate	45-60/min but may be as low as 30/min	Often <30/min
Stability of escape rhythm	Rate usually stable; asystole uncommon	Rate often unstable with moderate to high risk for ventricular asystole
Duration of high-grade AV block	Usually transient (2-3 days)	Usually transient but some form of AV conduction disturbance and/or intraventricular defect may persist
Associated mortality rate	Low unless associated with hypotension and/or with power failure or ventricular arrhythmias	High because of extensive infarction associated congestive heart failure
Pacemaker therapy		
Temporary	Rarely required; may be considered for bradycardia associated with left ventricular power failure, syncope, or angina	Should be considered in patients with anteroseptal infarction and acute bifascicular block
Permanent	Almost never indicated because the conduction defect is usually transient	Indicated for patients with high-grade AV block and block in the His-Purkinje system and those with a transient advanced AV block and associated bundle branch block

*Some studies suggest that a wide QRS escape rhythm (>0.12 second) following high-grade AV block in inferior infarction is associated with a worse prognosis.

LAD = left anterior descending coronary artery; LCX = left circumflex coronary artery; RCA = right coronary artery.

Modified from Antman EM, Rutherford JD (eds): *Coronary Care Medicine: A Practical Approach*. Boston, Martinus Nijhoff, 1986; and Dreifus LS, Fisch C, Griffin JC, et al: *Guidelines for implantation of cardiac pacemakers and antiarrhythmia devices*. *J Am Coll Cardiol* 18:1, 1991.

infarction usually develops gradually, often progressing from a first-degree or type I second-degree block.¹⁶² The escape rhythm is typically stable without asystole and often junctional, with a rate exceeding 40 beats/min and a narrow QRS complex in 70% of cases and a slower rate and wide QRS complex in the others. This form of complete AV block is often transient, may respond to pharmacologic antagonism of adenosine with methylxanthines, and resolves in most patients within a few days (Table 52-13).

Patients with inferior infarction often have concomitant ischemia or infarction of the AV node secondary to hypoperfusion of the AV node artery, but the His-Purkinje system usually escapes injury in such individuals. Patients with inferior STEMI and AV block have larger infarcts and more depressed right ventricular and left ventricular function than do patients with an inferior infarct and no AV block. As already noted, junctional escape rhythms with narrow QRS complexes occur commonly in this setting.

Pacing is not generally necessary in patients with inferior wall infarction and complete AV block because it is often transient in nature, but it is indicated if symptoms related to a ventricular rate emerge, if ventricular arrhythmias or hypotension is present, or if pump failure develops; atropine only rarely proves adequate in these patients. Only when complete heart block develops in less than 6 hours after the onset of symptoms is atropine likely to abolish the AV block or cause acceleration of the escape rhythm. In such cases the AV block is more likely to be transient and to be related to increases in vagal tone, as opposed to the more persistent block seen later in the course of STEMI, which generally requires cardiac pacing.

In patients with anterior infarction, third-degree AV block can occur suddenly 12 to 24 hours after the onset of infarction, although it is usually preceded by an intraventricular block and often a type II (not first-degree or type I) AV block. Such patients typically have unstable escape rhythms with wide QRS complexes and rates less than 40 beats/min; ventricular asystole may occur quite suddenly. In patients with anterior infarction, AV block generally develops as a result of extensive septal necrosis involving the bundle branches. The high rate of mortality in this group of patients with a slow idioventricular rhythm and wide QRS complex is the consequence of extensive myocardial necrosis resulting in severe left ventricular failure and frequently shock (Table 52-13).

Whether temporary transvenous pacing per se improves survival in patients with anterior STEMI remains controversial. Some physicians contend that ventricular pacing is of limited efficacy when used to correct a complete AV block in patients with anterior infarction in view of the poor prognosis in this group regardless of therapy. However, pacing protects against asystole and may protect against transient hypotension, with its attendant risks of extending the infarction and precipitating malignant ventricular tachyarrhythmias.

Intraventricular Block

The right bundle branch and the left posterior division have a dual blood supply from the left anterior descending and right coronary arteries, whereas the left anterior division is supplied by septal perforators originating from the left anterior descending coronary artery. Not all conduction blocks in patients with STEMI are complications of infarcts because almost half are already present at the time that the first ECG is recorded, and they may represent antecedent conduction abnormalities. When compared with patients without conduction defects, those with STEMI and bundle branch blocks have higher peak biomarker levels, lower ejection fractions, and increased in-hospital and long-term mortality rates.¹⁶³ In the prethrombolytic era, intraventricular conduction disturbances (i.e., block within one or more of the three subdivisions [fascicles] of the His-Purkinje system [the anterior and posterior divisions of the left bundle and the right bundle]) occurred in 5% to 10% of patients with STEMI. More recent series in the reperfusion era suggest that intraventricular blocks occur in approximately 2% to 5% of patients with MI.¹⁶³

Isolated Fascicular Blocks

An isolated left anterior divisional block is unlikely to progress to a complete AV block. Mortality is increased in these patients, although

not as much as in those with other forms of conduction block. The posterior fascicle is larger than the anterior fascicle, and in general, a larger infarct is required to block it. As a consequence, mortality is markedly increased. Complete AV block is not a frequent complication of either form of isolated divisional block.

Right Bundle Branch Block

This conduction defect alone can lead to AV block because it is often a new lesion associated with anteroseptal infarction. Isolated right bundle branch block is associated with an increased risk for mortality in patients with anterior STEMI even if complete AV block does not occur, but this appears to be the case only if accompanied by congestive heart failure.

Bifascicular Block, Including Left Bundle Branch Block

The combination of right bundle branch block with either left anterior or posterior divisional block or the combination of left anterior and posterior divisional blocks (i.e., left bundle branch block) is known as *biventricular* or *bifascicular* block. If a new block occurs in two of the three divisions of the conduction system, the risk for development of a complete AV block is quite high. Mortality is also high because of the occurrence of severe pump failure secondary to the extensive myocardial necrosis required to produce such an extensive intraventricular block.¹⁶⁴

Preexisting bundle branch block or divisional block is less often associated with the development of complete AV block in patients with STEMI than are conduction defects acquired during the course of the infarct. Biventricular block in the presence of prolongation of the PR interval (first-degree AV block) may indicate disease of the third subdivision rather than disease of the AV node and is associated with a greater risk for complete heart block than if first-degree AV block is absent.

Complete bundle branch block (either left or right), the combination of right bundle branch block and left anterior divisional (fascicular) block, and any of the various forms of trifascicular block are all more often associated with anterior than with inferoposterior infarction. All these forms are more frequent with large infarcts and in older patients and have a higher incidence of other accompanying arrhythmias than seen in patients without bundle branch block.

Use of Pacemakers in Patients with Acute Myocardial Infarction (See Chapter 36)

Temporary Pacing

Just as is the case for complete AV block, transvenous ventricular pacing has not resulted in a statistically demonstrable improvement in prognosis in patients with STEMI in whom intraventricular conduction defects develop. Temporary pacing is advisable in some of these patients, however, because of the high risk for development of a complete AV block. This category includes patients with new bilateral (bifascicular) bundle branch block (i.e., right bundle branch block with left anterior or posterior divisional block and alternating right and left bundle branch block); first-degree AV block adds to this risk. An isolated new block in only one of the three fascicles, even with PR prolongation and preexisting bifascicular block and a normal PR interval, poses somewhat less risk; these patients should be monitored closely, with insertion of a temporary pacemaker deferred unless a higher-degree AV block occurs.

Asystole

The presence of apparent ventricular asystole on monitor displays of continuously recorded ECGs may be misleading in that the rhythm may actually be fine VF. The predominance of VF as the cause of cardiac arrest in this setting suggests electrical countershock as initial therapy, even if definitive electrocardiographic documentation of this arrhythmia is not available.

Permanent Pacing

The advisability of permanent pacemaker insertion is complicated because not all sudden deaths in patients with STEMI and conduction defects are caused by high-grade AV block. A high incidence of late

VF occurs in CCU survivors with anterior STEMI complicated by either right or left bundle branch block. Therefore VF rather than asystole caused by failure of AV conduction and infranodal pacemakers could be responsible for late sudden death.

Long-term pacing is often helpful when complete heart block persists throughout the hospital phase in a patient with STEMI, when sinus node function is markedly impaired, or when type II second-degree or third-degree block occurs intermittently.¹⁶⁵ When high-grade AV block is associated with newly acquired bundle branch block or other criteria for conduction system impairment, prophylactic long-term pacing may be justified as well. Additional considerations that drive the decision to insert a permanent pacemaker include whether the patient is a candidate for an ICD or has severe heart failure that might be improved with biventricular pacing (see Chapters 25 and 26).

Supraventricular Tachyarrhythmias (See Chapters 37 and 38)

Sinus Tachycardia

This arrhythmia is typically associated with augmented sympathetic activity and may provoke transient hypertension or hypotension. Common causes are anxiety, persistent pain, left ventricular failure, fever, pericarditis, hypovolemia, pulmonary embolism, and the administration of drugs such as atropine, epinephrine, or dopamine; rarely, it occurs in patients with atrial infarction. Sinus tachycardia is particularly common in patients with anterior infarction, especially in those with significant accompanying left ventricular dysfunction. It is an undesirable rhythm in patients with STEMI because it results in augmentation of myocardial oxygen consumption, as well as a reduction in the time available for coronary perfusion, thereby intensifying the myocardial ischemia and/or external myocardial necrosis. Persistent sinus tachycardia can signify persistent heart failure and, in these circumstances, connotes a poor prognosis and excess mortality. An underlying cause should be sought and appropriate treatment instituted, such as analgesics for pain; diuretics for heart failure; oxygen, beta blockers, and nitroglycerin for ischemia; and aspirin for fever or pericarditis. Treating sinus tachycardia caused by pain, anxiety, or fever with beta blockers is reasonable, but beta blockers are contraindicated in patients who are tachycardic because of pump failure.

Atrial Flutter and Fibrillation

Atrial flutter and atrial fibrillation are usually transient in patients with STEMI; they are typically a consequence of augmented sympathetic stimulation of the atria and often occur in patients with left ventricular failure, pulmonary emboli in which the arrhythmia intensifies hemodynamic deterioration, or atrial infarction (see Table 52-12). The increased ventricular rate and loss of the atrial contribution to left ventricular filling can result in a significant reduction in cardiac output. Atrial fibrillation during STEMI is associated with increased mortality and stroke, particularly in patients with anterior wall infarction¹⁶⁶—but because it is more common in patients with clinical and hemodynamic manifestations of extensive infarction and a poor prognosis, atrial fibrillation is probably a marker of a poor prognosis with only a small independent contribution to increased mortality.¹⁶⁶

Management

Atrial flutter and fibrillation in patients with STEMI are treated in a manner similar to these conditions in other settings (see Chapter 38). If the arrhythmia is causing ongoing hypotension, ischemia, or heart failure, cardioversion should be considered. In stabilized patients and in the absence of contraindications, a beta blocker should be administered after STEMI; in addition to several other benefits, these agents help slow the ventricular rate should atrial fibrillation recur. Digitalis may also help slow the ventricular rate when atrial fibrillation develops after STEMI in the setting of ventricular dysfunction.¹⁶⁷ In addition, amiodarone may be considered in this situation. Patients with recurrent episodes of atrial fibrillation should be treated

with oral anticoagulants (to reduce the risk for stroke), even if sinus rhythm is present at the time of hospital discharge, because no antiarrhythmic regimen can be relied on to completely suppress atrial fibrillation.

OTHER COMPLICATIONS

Recurrent Chest Discomfort

Evaluation of postinfarction chest discomfort is sometimes complicated by previous abnormalities on the ECG and a vague description of the discomfort by the patient, who either may be exquisitely sensitive to fleeting discomfort or may deny a potential recrudescence of symptoms. The critical task for clinicians is to distinguish recurrent angina or infarction from nonischemic causes of discomfort that might be caused by infarct expansion, pericarditis, pulmonary embolism, and non-cardiac-related conditions. Ischemic causes to consider include acute reocclusion of an initially recanalized or stented vessel, mechanical or thrombotic occlusion of a side branch or distal vessel during an initial PCI, new ischemia in a non-infarct-related coronary artery that was also stenosed but not occluded, and coronary spasm. Important diagnostic maneuvers include repeated physical examination, repeated ECG, and assessment of the response to sublingual nitroglycerin, 0.4 mg. (The use of noninvasive diagnostic evaluation for recurrent ischemia in patients whose symptoms appear only with moderate or higher levels of exertion is discussed elsewhere in this chapter.)

Recurrent Ischemia and Reinfarction

The incidence of postinfarction angina with and without reinfarction is significantly reduced in patients undergoing primary PCI for STEMI versus fibrinolysis. Additionally, in high-risk patients with STEMI who were treated with fibrinolysis, transfer for PCI within 6 hours after fibrinolysis is also associated with significantly fewer ischemic complications than is treatment with fibrinolysis alone.⁷² More effective antiplatelet and antithrombin therapies have also reduced the rate of recurrent ischemic events following STEMI.¹ Consequently, the incidence of early recurrent ischemic events in STEMI patients treated by immediate or delayed PCI is now in a range of less than 5%.

Diagnosis

Extension of the original zone of necrosis or reinfarction into a separate myocardial zone can be a difficult diagnosis, especially within the first 24 hours after the index event. Diagnostic criteria have been established,¹⁶⁸ but discrimination of a new myocardial infarction discrete from the initial STEMI is often challenging because both cardiac markers may remain elevated as a result of the initial infarction and distinguishing changes of the normal evolution after the index infarction from those caused by recurrent infarction may not be possible on the ECG. Recurrent infarction should be strongly considered, however, when dynamic recurrent ST-segment elevation is noted on the ECG.

Pericarditis should also be considered in such patients. The presence of a rub and lack of responsiveness to nitroglycerin may be useful in distinguishing pericardial discomfort, but doing so on clinical grounds is frequently challenging, and diagnostic coronary angiography may be necessary to exclude acute native vessel or stent thrombosis. The predominant angiographic predictors of reinfarction in patients undergoing primary PCI include a final coronary stenosis greater than 30%, post-PCI coronary dissection, and post-PCI intracoronary thrombus.¹⁶⁹

Prognosis

Regardless of whether postinfarction angina is persistent or limited, its presence is important because of the associated higher short-term morbidity rate. Reinfarction is linked to higher rates of in-hospital complications (congestive heart failure, AV block) and early and long-term mortality.¹⁷⁰ Presumably, the higher mortality rate is related to the larger mass of myocardium, the function of which becomes compromised.

Management

Patients with ST-segment re-elevation and the appropriate clinical findings should be referred for urgent catheterization and PCI (see Fig. 52-1) unless pericarditis or other post-MI complications are the cause; repeated fibrinolysis can be considered if PCI is not available. In patients believed to have recurrent ischemia in the absence of ST elevation concerning for ongoing injury and who do not have evidence of hemodynamic compromise, an attempt should be made to control symptoms with sublingual or intravenous nitroglycerin and intravenous beta blockade to slow the heart rate to 60 beats/min. When hypotension, congestive heart failure, or ventricular arrhythmias develop during recurrent ischemia, urgent catheterization and revascularization are indicated.

High-risk patients with STEMI who undergo fibrinolysis may benefit from a strategy of routine referral for catheterization and revascularization (3 to 24 hours; see Fig. 52-13).⁷² Trials that compared primary PCI with PCI performed as soon as possible after a preparatory pharmacologic regimen had been administered, however, have not shown such a facilitated PCI approach to be more effective than primary PCI, and mortality may even increase because of excessive bleeding in the facilitated PCI group.¹

Finally, with increasing use of PCI for the management of patients with STEMI, clinicians should be alert to the problem of stent thrombosis as a cause of recurrent ischemia. Stent thrombosis can occur acutely (hours to days after deployment of a stent) or in a more subacute fashion (many months after deployment of a stent) (see Chapter 55).

Pericardial Effusion and Pericarditis (See Chapter 71)

Pericardial Effusion

Effusions are generally detected echocardiographically, and their incidence varies with technique, criteria, and laboratory expertise.¹⁷¹ Effusions are more common in patients with anterior STEMI and with larger infarcts and when congestive failure is present. Most pericardial effusions that occur following STEMI do not cause hemodynamic compromise. The reabsorption rate of a postinfarction pericardial effusion is slow, with resolution often taking several months. The presence of an effusion does not indicate that pericarditis is present; although they may occur together, most effusions develop without other evidence of pericarditis. When tamponade does occur, it is usually caused by ventricular rupture or hemorrhagic pericarditis.

Pericarditis

Pericarditis can produce pain as early as the first day and as late as 8 weeks after STEMI. The pain of pericarditis may be confused with that resulting from postinfarction angina, recurrent infarction, or both. An important distinguishing feature is radiation of the pain to either trapezius ridge, a finding that is nearly pathognomonic of pericarditis and rarely seen with ischemic discomfort. Additionally, the discomfort of pericarditis usually becomes worse during a deep inspiration, but it can be relieved or diminished when the patient sits up and leans forward.

Transmural MI, by definition, extends to the epicardial surface and can cause local pericardial inflammation. An acute fibrinous pericarditis (pericarditis epistenocardica) occurs commonly after transmural infarction, but most patients do not report any symptoms from this process. Although transient pericardial friction rubs are relatively common within the first 48 hours in patients with transmural infarction, pain or electrocardiographic changes occur much less often. The development of a pericardial rub, however, appears to correlate with a larger infarct and greater hemodynamic compromise.

Although anticoagulation clearly increases the risk for hemorrhagic pericarditis early after STEMI, this complication does not occur with sufficient frequency during heparinization or following fibrinolytic therapy to warrant absolute prohibition of such agents when a rub is present. Nevertheless, detection of a pericardial effusion on echocardiography is usually an indication for discontinuation of anticoagulation. In patients in whom continuation or initiation of

anticoagulant therapy is strongly indicated (e.g., during cardiac catheterization), heightened monitoring of clotting parameters and observation for clinical signs of possible tamponade are necessary. Late pericardial constriction caused by anticoagulant-induced hemopericardium has been reported.

Treatment of pericardial discomfort consists of aspirin, but usually in doses higher than prescribed routinely following infarction—doses of 650 mg orally as often as every 4 hours may be necessary. Nonsteroidal anti-inflammatory drugs (NSAIDs) and steroids should be avoided because they may interfere with myocardial scar formation.¹⁷²

Dressler Syndrome

Also known as *post-myocardial infarction syndrome*, Dressler syndrome usually occurs 1 to 8 weeks after infarction. Dressler cited an incidence of 3% to 4% of all patients with MI in 1957, but the incidence has decreased dramatically since that time. Clinically, patients with Dressler syndrome have malaise, fever, pericardial discomfort, leukocytosis, an elevated sedimentation rate, and a pericardial effusion. At autopsy, individuals with this syndrome usually demonstrate localized fibrinous pericarditis containing polymorphonuclear leukocytes. The cause of this syndrome is not clearly established, although detection of antibodies to cardiac tissue has raised the notion of an immunopathologic process. Treatment is with aspirin, 650 mg as often as every 4 hours, and in large doses this is effective.¹⁷² Glucocorticosteroids and NSAIDs are best avoided in patients with Dressler syndrome within 4 weeks of STEMI because of their potential to impair infarct healing, cause ventricular rupture, and increase coronary vascular resistance.¹⁷²

Venous Thrombosis and Pulmonary Embolism

Almost all peri-MI pulmonary emboli originate from thrombi in the veins of the lower extremities; much less commonly, they originate from mural thrombi overlying an area of right ventricular infarction. Bed rest and heart failure predispose to venous thrombosis and subsequent to pulmonary embolism, and both these conditions occur commonly in patients with STEMI, particularly in those with large infarcts. At a time when patients with STEMI were routinely subjected to prolonged periods of bed rest, significant pulmonary embolism was found in more than 20% of individuals with STEMI examined at autopsy, and massive pulmonary embolism accounted for 10% of deaths from MI. In contemporary practice, with early mobilization and the widespread use of low-dose anticoagulant prophylaxis, especially with LMWH, pulmonary embolism has become an uncommon cause of death in patients with STEMI. When pulmonary embolism does occur in patients with STEMI, management is generally along the lines described for patients without infarction (see Chapter 73).

Left Ventricular Aneurysm

The term *left ventricular aneurysm* (often termed *true aneurysm*) is generally reserved for a discrete, dyskinetic area of the left ventricular wall with a broad neck (to differentiate it from a pseudoaneurysm caused by a contained myocardial rupture). Dyskinetic or akinetic areas of the left ventricle are far more common than true aneurysms after STEMI. True left ventricular aneurysms probably develop in less than 5% of all patients with STEMI.¹⁷³ The wall of a true aneurysm is thinner than the wall of the rest of the left ventricle (see Fig. 52-29), and it is usually composed of fibrous tissue, as well as necrotic muscle occasionally mixed with viable myocardium.

Pathogenesis

Aneurysm formation presumably occurs when intraventricular tension stretches the noncontracting infarcted heart muscle and thus produces expansion of the infarct, a relatively weak, thin layer of necrotic muscle, and fibrous tissue that bulges with each cardiac contraction. With the passage of time, the wall of the aneurysm

becomes more densely fibrotic, but it continues to bulge with systole and causes some of the left ventricular stroke volume during each systole to be ineffective.

Total occlusion of a poorly collateralized left anterior descending coronary artery is generally associated with aneurysm formation after anterior STEMI. An aneurysm rarely occurs with multivessel disease when either extensive collaterals or a nonoccluded left anterior descending artery is present. Aneurysms usually range from 1 to 8 cm in diameter. They occur approximately four times more often at the apex and in the anterior wall than in the inferoposterior wall. The overlying pericardium generally adheres densely to the wall of the aneurysm, which may even become partially calcified after several years. True left ventricular aneurysms (in contrast to pseudoaneurysms) rarely rupture soon after development. Late rupture, when the true aneurysm has become stabilized by the formation of dense fibrous tissue in its wall, almost never occurs.

Diagnosis

The presence of persistent ST-segment elevation in an electrocardiographic area of infarction, classically thought to suggest aneurysm formation, indicates a large infarct with a regional wall motion abnormality but does not necessarily imply an aneurysm. The diagnosis of aneurysm is best made noninvasively by an echocardiographic study, by MRI, or by left ventriculography at the time of cardiac catheterization.

Prognosis and Treatment

A left ventricular aneurysm increases the risk for mortality, even when compared with that in patients with a comparable left ventricular ejection fraction. Death in these patients is frequently sudden and presumably related to the relatively high incidence of ventricular tachyarrhythmias that occur with aneurysms.¹⁷⁴ With loss of shortening from the area of the aneurysm, the remainder of the ventricle may become hyperkinetic to compensate, but with relatively large aneurysms, complete compensation is impossible. Stroke volume falls, or if maintained, it is at the expense of an increase in end-diastolic volume, which in turn leads to increased wall tension and myocardial oxygen demand. Heart failure may ensue, and angina may appear or worsen.

Aggressive management of STEMI, including prompt reperfusion, may diminish the incidence of ventricular aneurysms. Surgical aneurysmectomy generally succeeds only if contractile performance in the nonaneurysmal portion of the left ventricle is relatively preserved. In such circumstances, when the operation is performed for worsening heart failure or angina, operative mortality is relatively low and clinical improvement can be expected. Several surgical techniques for ventricular reconstruction have been developed to maintain as normal a left ventricular shape as possible.¹⁷⁵ Because of the risk for mural thrombosis and systemic embolization, long-term oral anticoagulation with warfarin may be considered in patients with a residual left ventricular aneurysm after STEMI.

Left Ventricular Thrombus and Arterial Embolism

Endocardial inflammation and the relative stasis of blood during the acute phase of infarction probably provide a thrombogenic surface for clots to form in the left ventricle. With extensive transmural infarction of the septum, however, mural thrombi may overlie infarcted myocardium in both ventricles. The incidence of left ventricular thrombus formation after STEMI appears to have dropped from approximately 20% to 5% with more aggressive use of antithrombotic strategies, but varying imaging techniques will influence detection rates.¹⁷⁶ Prospective studies have suggested that patients in whom a mural thrombus develops early (within 48 to 72 hours of infarction) have an extremely poor early prognosis, with a high rate of mortality from the complications of a large infarction (shock, reinfarction, rupture, and ventricular tachyarrhythmia), rather than emboli from the left ventricular thrombus.

Even though a mural thrombus adheres to the endocardium overlying the infarcted myocardium, superficial portions of it can become

detached and produce systemic arterial emboli. Although estimates vary because of patient selection, approximately 10% of mural thrombi result in systemic embolization. Echocardiographically detectable features suggesting that a given thrombus is more likely to embolize include increased mobility and protrusion into the ventricular chamber, visualization on multiple views, and contiguous zones of akinesis and hyperkinesis. MRI techniques can also be used to characterize left ventricular thrombi and assist in prediction of the risk for embolism.¹⁷⁶

Management

Data from previous trials with limited sample sizes suggested that anticoagulation (intravenous heparin or high-dose subcutaneous heparin) reduces the development of left ventricular thrombi by 50%, but because of the low event rate, demonstrating a reduction in the incidence of systemic embolism was not possible. Fibrinolysis reduces the rate of thrombus formation and the character of the thrombi so that they are less protuberant. Of note, however, the data from fibrinolytic trials are difficult to interpret because of the confounding effect of antithrombotic therapy with heparin. Recommendations for anticoagulation vary considerably, and fibrinolysis has precipitated fatal embolization. Moreover, few data from the era of dual antiplatelet therapy after primary PCI are available to make decisions. Nevertheless, anticoagulation for 3 to 6 months with warfarin is reasonable for many patients with demonstrable mural thrombi. For patients with STEMI and anterior apical akinesis or severe dyskinesia, a limited course of anticoagulant therapy may also be considered.¹

CONVALESCENCE, DISCHARGE, AND POST-MYOCARDIAL INFARCTION CARE

The transition to outpatient care after STEMI is a critical one. Post-hospital systems of care designed to reduce hospital readmissions should be used to facilitate coordinated, evidence-based outpatient care for all patients with STEMI.^{1,177}

Timing of Hospital Discharge

In practice, the timing of discharge from the hospital is variable. Patients with STEMI are at risk for late in-hospital mortality from recurrent ischemia or infarction, hemodynamically significant ventricular arrhythmias, and severe congestive heart failure. Risk indicators for mortality in the hospital include significant congestive heart failure as evidenced by persistent sinus tachycardia and pulmonary congestion, recurrent VT and VF, new atrial fibrillation or flutter, intraventricular conduction delays or heart block, anterior location of infarction, and recurrent episodes of angina with marked ST-segment abnormalities at low activity levels (see the section [Risk Stratification after ST-Elevation Myocardial Infarction](#)).

Aggressive reperfusion protocols with PCI or fibrinolytics can reduce the length of hospital stay without compromising mortality after discharge.^{178,179} In patients believed to have successfully undergone reperfusion, the absence of early sustained ventricular tachyarrhythmias, hypotension, or heart failure, coupled with a well-preserved left ventricular ejection fraction, predicts a low risk for late complications in the hospital. Such patients appear to be suitable candidates for discharge from the hospital in less than 5 days from the onset of symptoms.¹⁷⁹ Most complications that would preclude early discharge occur within the first 3 days of admission; therefore patients suitable for early discharge can be identified early during the hospitalization. Several controlled trials and many uncontrolled trials of early discharge after STEMI have failed to show any increase in risk in patients appropriately selected for early discharge.^{178,179}

Following STEMI, patients are often eager for information, anxious, in need of reassurance, confused by misinformation and previous impressions, and capable of counterproductive denial. The hospitalization after STEMI provides ample opportunities to begin the rehabilitation process. The decision regarding timing of discharge in

patients with uncomplicated STEMI should take into account the patient's psychological state after STEMI, the adequacy of dose titration for essential drugs such as beta blockers and inhibitors of the RAAS, and the availability and timing of follow-up with visiting nurses and the patient's primary care physician. In patients who have experienced a complication, discharge is deferred until their condition has been stable for several days and it is clear that they have responded appropriately to any interventions.

Counseling

Before discharge from the hospital, all patients should receive detailed instruction concerning physical activity. Initially, this should consist of walking at home but avoidance of isometric exercise such as lifting. In addition, the patient should be given fresh nitroglycerin tablets and be instructed in their use (see Chapter 54) and should receive instructions for any other medications prescribed. Graded resumption of activity should be encouraged, ideally as part of a monitored cardiac rehabilitation program (see Chapters 47 and 79). Many approaches have been used, ranging from formal rigid guidelines to general advice advocating moderation and avoidance of any activity that evokes symptoms. Sexual counseling, often overlooked during recovery from STEMI, should be included in the educational process.¹⁸⁰ In addition, physicians should explicitly discuss the risk associated with continued smoking and offer assistance in cessation, along with nicotine replacement therapy in appropriate patients.^{1,181}

Some evidence indicates that behavioral alteration is possible after recovery from STEMI and that this may improve the prognosis. Patients with STEMI should be referred to a postdischarge cardiac rehabilitation program with supervised physical exercise and an educational component.¹⁸² Given the relationship between depression and STEMI, psychosocial intervention programs can decrease symptoms of depression and are a useful adjunct to standard cardiac rehabilitation programs after STEMI¹⁸³ (see Chapters 47 and 86).

Risk Stratification after ST-Elevation Myocardial Infarction

The process of risk stratification following STEMI occurs in several stages: initial findings, in-hospital course (CCU, intermediate care unit), and at the time of hospital discharge. The tools used to form an integrated and dynamic assessment of the patient consist of baseline demographic information; serial ECGs and serum and plasma cardiac biomarker measurements; hemodynamic monitoring data; a variety of noninvasive tests; and if performed, the findings at cardiac catheterization. These findings, integrated with the occurrence of in-hospital complications, can provide information regarding survival.

Initial Findings

Certain demographic and historical factors portend a worse prognosis in patients with STEMI, including age older than 65 years, a history of diabetes mellitus, previous angina pectoris, and previous MI (see Fig. 52-8). Diabetes mellitus, in particular, appears to confer a more than 40% increase in adjusted risk for death by 30 days (see Chapter 61).¹⁸⁴ Surviving diabetic patients also experience a more complicated post-MI course, including a greater incidence of postinfarction angina, infarct extension, and heart failure. These higher rates of complications probably relate to the extensive accelerated atherosclerosis and higher risk for thrombosis and heart failure associated with diabetes mellitus.

In addition to playing a central role in the decision pathway for the management of patients with ACSs based on the presence or absence of ST-segment elevation, the 12-lead ECG carries important prognostic information.⁶³ Mortality is greater in patients experiencing anterior wall STEMI than in those with inferior STEMI, even when corrected for infarct size. Patients with right ventricular infarction complicating inferior infarction, as suggested by ST-segment elevation in V_4R , have greater mortality rate than do patients sustaining an inferior infarction without right ventricular involvement. Patients with multiple leads showing ST elevation and a high sum of ST-segment elevation

have an increased mortality rate, especially if their infarct is anterior in location. Patients whose ECGs demonstrate persistent advanced heart block (e.g., type II second-degree or third-degree AV block) or new intraventricular conduction abnormalities (bifascicular or trifascicular) in the course of STEMI have a worse prognosis than do patients without these abnormalities. The influence of high degrees of heart block has particular importance in patients with right ventricular infarction because such patients have a markedly increased mortality risk.⁶³ Other electrocardiographic findings that augur poorly are persistent horizontal or downsloping ST-segment depression, Q waves in multiple leads, evidence of right ventricular infarction accompanying inferior infarction, ST-segment depression in anterior leads in patients with inferior infarction, and atrial arrhythmias (especially atrial fibrillation).

Several validated clinical risk stratification tools may be used at initial evaluation to assess the short- and long-term risk for death after MI.⁶³ In addition to the patient's age and historical factors such as diabetes and previous MI, clinical signs of heart failure, including tachycardia and hypotension, are common in many of these clinical risk assessment scores.

Hospital Course

Hospital mortality from STEMI depends directly on the severity of left ventricular dysfunction. Risk stratification via physical findings, estimation of infarct size, and in appropriate patients, invasive hemodynamic monitoring provides an assessment of the likelihood of a complicated hospital course and may also identify important abnormalities, such as hemodynamically significant mitral regurgitation, that convey an adverse long-term prognosis (see Table 52-9). In particular, the development of heart failure after MI entails a higher risk for sudden cardiac death.¹⁸⁵ Recurrent infarction and new stroke during hospitalization for STEMI also, not surprisingly, confer a higher risk for death.

Assessment at Hospital Discharge

Both short- and long-term survival after STEMI depend on three major factors: resting left ventricular function, residual potentially ischemic myocardium, and susceptibility to serious ventricular arrhythmias. The most important of these factors is the state of left ventricular function (see Fig. 52-23).⁶³ The second most important factor is how the severity and extent of the obstructive lesions in the coronary vascular bed perfusing residual viable myocardium affect the risk for recurrent infarction, additional myocardial damage, and serious ventricular arrhythmias. Thus survival is related to the quantity of myocardium that has become necrotic and the quantity at risk of becoming necrotic. At one end of the spectrum, the prognosis is best for patients with normal intrinsic coronary vessels whose completed infarction constitutes a small fraction (5%) of the left ventricle as a consequence of a coronary embolus and who have no jeopardized myocardium. At the other extreme are patients with a massive infarct and left ventricular failure whose residual viable myocardium is perfused by markedly obstructed vessels. Progression of atherosclerosis or lowering of perfusion pressure in these vessels impairs the function and viability of the residual myocardium on which left ventricular function depends. Revascularization may reduce the threat to the jeopardized myocardium even in such patients. The third risk factor, susceptibility to serious arrhythmias, is reflected in ventricular ectopic activity and other indicators of electrical instability, such as reduced heart rate variability or baroreflex sensitivity and abnormal findings on a signal-averaged ECG.⁶³ All these factors identify patients at increased risk for death.

Assessment of Left Ventricular Function

The left ventricular ejection fraction may be the most easily assessed measurement of left ventricular function and is extremely useful for risk stratification (see Fig. 52-23). However, imaging of the left ventricle at rest may not adequately distinguish among infarcted, irreversibly damaged, and stunned or hibernating myocardium. To circumvent this difficulty, various techniques have been investigated to assess the extent of residual viable myocardium—including

exercise and pharmacologic stress echocardiography, stress radionuclide ventricular angiography, perfusion imaging in conjunction with pharmacologic stress, positron emission tomography, and gadolinium-enhanced MRI.^{186,187} All these techniques can be performed safely in postinfarction patients. Because no study has clearly shown one imaging modality to be superior to the others, clinicians should be guided in their selection of ventricular imaging technique by the availability and level of expertise with a given modality at their local institution.¹⁸⁸

Assessment of Myocardial Ischemia

Because of the adverse consequences of recurrent MI after STEMI, assessing a patient's risk for future ischemia and infarction is important. PredischARGE noninvasive testing for ischemia provides valuable information about the presence of residual ischemia in patients who have not undergone coronary angiography during the initial management of STEMI and may also be useful in assessing the functional significance of any angiographically significant coronary stenoses identified at angiography but not revascularized (see [Table 52-6](#)). In the latter case, stress imaging to localize ischemia may be useful.

EXERCISE TESTING. An exercise test also offers an opportunity to formulate a more precise exercise prescription and helps boost patients' confidence in their ability to conduct their daily activities after discharge. Patients who are unable to exercise can be evaluated via a pharmacologic stress protocol with echocardiography or perfusion imaging. Treadmill exercise testing after STEMI has traditionally used a submaximal protocol that requires the patient to exercise until symptoms of angina appear, electrocardiographic evidence of ischemia is seen, or a target workload (5 metabolic equivalents) has been reached, whichever comes first (see [Chapter 47](#)). Symptom-limited exercise tests can be performed safely before discharge in patients with an uncomplicated course after infarction. Variables derived from exercise tests after STEMI that have been evaluated for their ability to predict the occurrence of death or recurrent nonfatal infarction include the development and magnitude of ST-segment depression, the development of angina, exercise capacity, and the systolic blood pressure response during exercise.⁶³

Assessment for Electrical Instability

After STEMI, patients are at greatest risk for the development of sudden cardiac death caused by malignant ventricular arrhythmias in the first 1 to 2 years.⁶³ Multiple techniques have been proposed to stratify patients into those who are at increased risk for sudden death following STEMI: measurement of QT dispersion (variability in QT intervals between ECG leads), ambulatory ECGs for detection of ventricular arrhythmias (Holter monitoring), invasive electrophysiologic testing, recording of a signal-averaged ECG (a measure of delayed, fragmented conduction in the infarct zone), and measurement of heart rate variability (beat-to-beat variability in R-R intervals) or baroreflex sensitivity (slope of a line relating beat-to-beat change in the sinus rate in response to alteration of blood pressure), but none of these approaches have proved sufficiently useful for routine practice.⁶³

Despite the increased risk for arrhythmic events following STEMI in patients who are found to have abnormal results on one or more of the noninvasive tests described earlier, several points should be emphasized. The low positive predictive value (<30%) of the noninvasive screening tests limits their usefulness when viewed in isolation. Although the predictive value of screening tests can be improved by combining several of them together, the therapeutic implications of an increased risk profile for arrhythmic events have not been established. The reductions in mortality achievable with the general use of beta blockers, ACE inhibitors, aspirin, and revascularization when appropriate after infarction, coupled with concerns about the efficacy and safety of antiarrhythmic drugs and the cost of implanted defibrillators, leave considerable uncertainty about the therapeutic implications of an abnormal noninvasive test result for electrical instability in an asymptomatic patient. Action by clinicians on the results of an abnormal finding in asymptomatic patients should await additional data on patient outcomes. Management of patients with

sustained, hemodynamically compromising arrhythmias is discussed in [Chapters 35 through 38](#).

Prophylactic Antiarrhythmic Therapy

Although antiarrhythmic therapy can control atrial and ventricular arrhythmias effectively in many patients, routine use of prophylactic antiarrhythmic drug therapy, with the exception of beta blockers, does not improve outcome and, with some agents, increases the risk for death.¹ The most notable postinfarction trial in this area was CAST (Cardiac Arrhythmia Suppression Trial), which tested whether encainide, flecainide, or moricizine for suppression of ventricular arrhythmias detected on ambulatory electrocardiographic monitoring would reduce the risk for cardiac arrest and death; however, CAST was stopped prematurely because of increased mortality in the active treatment groups. The SWORD (Survival With ORal D-sotalol) trial was similarly stopped prematurely because of increased mortality in the active treatment group. In contrast, CAMIAT (Canadian Amiodarone Myocardial Infarction Trial) showed that amiodarone reduces the frequency of ventricular premature depolarization in patients with recent MI and that this reduction correlated with lowering of arrhythmic death or resuscitation from VF. However, 42% of patients discontinued use of amiodarone during maintenance therapy in CAMIAT because of intolerable side effects. EMIAT (European Amiodarone Myocardial Infarction Trial) showed a reduction in arrhythmic death after MI in patients with depressed left ventricular function, but total mortality and other cardiovascular-related mortality did not decrease.

The routine use of antiarrhythmic agents (including amiodarone) therefore cannot be recommended. Although trials that included post-STEMI patients in the study population have shown significant reductions in mortality in those randomly assigned to ICD implantation versus conventional medical therapy (see [Chapter 36](#)), early implantation of an ICD in the first few weeks after MI has not shown benefit.¹⁸⁹ Routine risk stratification to guide ICD placement early after STEMI is therefore not recommended; reassessment of left ventricular function 40 days or longer after STEMI may be used to guide consideration of an ICD for primary prevention of sudden cardiac death ([Fig. 52-34](#)).^{189,190} Trials of strategies for prevention and treatment of arrhythmias, including the use of wearable external defibrillators,¹⁹¹ during the early period after STEMI are ongoing.

Secondary Prevention of Acute Myocardial Infarction (See Chapters 42 and 45)

Patients who survive the initial course of STEMI still have considerable risk for recurrent events, thus rendering efforts imperative to reduce this risk.

Cardiac Rehabilitation

Contemporary exercise-based cardiac rehabilitation after STEMI is aimed at increasing functional capacity, reducing disability, improving quality of life, modifying coronary risk factors, and reducing morbidity and mortality rates.¹⁹²⁻¹⁹⁴ The key components of cardiac rehabilitation include patient assessment; ongoing medical surveillance; nutritional counseling; management of hypertension, lipids, and diabetes mellitus; cessation of smoking; psychosocial counseling; physical activity counseling; exercise training; and pharmacologic treatment, as appropriate.¹⁹⁵ When compared with usual care, cardiac rehabilitation is associated with lower total and cardiac mortality, but despite these outcomes, cardiac rehabilitation services remain vastly underused.¹

Lifestyle Modification

Efforts to improve survival and quality of life after MI that relate to lifestyle modification of known risk factors are considered in [Chapter 42](#). Of these, cessation of smoking and control of hypertension are probably the most important. Use of hospital-based smoking cessation programs and referral to cardiac rehabilitation programs have led to successful smoking cessation.¹⁹⁶

Depression (See Chapter 86)

Physicians caring for patients following STEMI need to be sensitive to the prevalence of major depression after infarction.¹⁹⁷ This problem is independently associated with higher risk for death. In addition, lack of an emotionally supportive network in the patient's environment after discharge is associated with an increased risk for recurrent cardiac events. The precise mechanisms relating depression and lack of social support to a worse prognosis after STEMI are not clear, but one possibility is lack of adherence to prescribed treatments, a behavior that has been associated with increased risk for mortality after infarction. Therefore a comprehensive cardiac rehabilitation program that includes primary health care personnel who counsel patients and make home visits can reduce the rate of rehospitalization for recurrent ischemia and infarction.¹⁹⁸

FIGURE 52-34 **A**, DINAMIT trial and algorithm for implantation of an ICD in patients with STEMI but without VF or sustained VT more than 48 hours after STEMI. DINAMIT was a randomized, open-label study comparing ICD with no ICD therapy 6 to 40 days after an MI in 674 patients who also had a left ventricular ejection fraction (LVEF) of 35% or less and impaired cardiac autonomic function. The study concluded that ICD therapy was associated with a reduction in the rate of death from arrhythmias but that this advantage was offset by an increase in deaths from other causes. **B**, The appropriate management path is based on measurement of LVEF; measurements obtained 3 days or less after STEMI should be repeated before proceeding with the algorithm. Patients with an LVEF of less than 30% to 40% at least 40 days after STEMI are referred for insertion of an ICD if they are in New York Heart Association (NYHA) class II or III. Patients with a more depressed LVEF of less than 30% to 35% are referred for ICD implantation even if they are NYHA class I because of their increased risk for sudden cardiac death. Patients with preserved left ventricular function (LVEF > 40%) do not receive an ICD and are treated with medical therapy after STEMI. (**A**, From Hohnloser SH, Kuck KH, Dorian P, et al: Prophylactic use of an implantable cardioverter-defibrillator after acute myocardial infarction. *N Engl J Med* 351:2481, 2004; **B**, modified from Zipes DP, Camm AJ, Borggrefe M, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: A report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for Management of Patients with Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death]. Developed in collaboration with the European Rhythm Association and the Heart Rhythm Society. *Circulation* 114:e385, 2006.)

Modification of Lipid Profile (See Chapters 42 and 45)

A target low-density lipoprotein cholesterol level of less than 100 mg/dL with an optimal target of less than 70 mg/dL has been recommended in patients with clinically evident CAD.¹⁹⁹ High-intensity statin therapy should be initiated or continued in all patients with STEMI and no contraindications to its use.¹ Obtaining a lipid profile on admission is reasonable in all patients admitted with acute infarction. Total cholesterol levels may fall 24 to 48 hours after infarction.

Antiplatelet Agents (See also Chapter 82)

On the basis of compelling data from the Antiplatelet Trialists' Collaboration of a 22% reduction in the risk for recurrent infarction, stroke, or vascular death in high-risk vascular patients receiving prolonged antiplatelet therapy, in the absence of true aspirin allergy all patients with STEMI should receive 75 to 325 mg of aspirin daily indefinitely, with 81 mg being the preferred maintenance dose.^{1,154} Additional benefits of long-term aspirin therapy that can accrue in patients with STEMI include an increased likelihood of patency of the infarct artery and smaller infarcts if MI recurs. Patients with true aspirin allergy can be treated with clopidogrel (75 mg once daily) on the basis of experience in patients with unstable angina/non-ST-segment elevation MI. In the absence of contraindications, all patients after STEMI should receive a platelet inhibitor in addition to aspirin for 12 months according to one of the following regimens: clopidogrel (75 mg/day) in patients with STEMI treated with or without PCI, prasugrel (10 mg/day) in patients treated with PCI, or ticagrelor (90 mg twice daily) in patients to be treated with PCI.¹ In patients treated with PCI, prasugrel and ticagrelor have been found to be superior to clopidogrel and are recommended as preferred in some professional guidelines.⁴ However, in some practice environments, economic or formulary barriers may render access to prasugrel or ticagrelor difficult for some patients. Given the critical importance of dual antiplatelet therapy in patients who have received drug-eluting stents, access to a P2Y₁₂ inhibitor must be ensured. The twice-daily dosing regimen for ticagrelor should be considered for patients with concern regarding adherence to this regimen. The optimum duration of treatment with dual antiplatelet therapy remains uncertain. Nonetheless, its benefit has continued after 30 days, and for now, a P2Y₁₂ inhibitor along with aspirin should be administered to most patients for at least 1 year after STEMI, with aspirin treatment being maintained indefinitely.¹

Inhibition of the Renin-Angiotensin-Aldosterone System

See Inhibition of the Renin-Angiotensin-Aldosterone System in the section Pharmacologic Therapy. To prevent late remodeling of the left ventricle and to decrease the likelihood of recurrent ischemic events, we advocate indefinite therapy with an ACE inhibitor in patients with heart failure, a moderate decrease in global ejection fraction, or a large regional wall motion abnormality, even in the presence of a normal global ejection fraction. Other candidates for long-term management with ACE inhibitors or ARBs are discussed in [Chapter 54](#).

Beta-Adrenergic Blocking Agents

Meta-analyses of trials from the prethrombolytic era involving more than 24,000 patients who received beta blockers in the convalescent phase of STEMI have shown a 23% reduction in long-term mortality. In most patients who have beta blockade initiated during the convalescent phase of STEMI, the reduction in long-term mortality is probably caused by the combination of an antiarrhythmic effect (prevention of sudden death) and prevention of reinfarction.

Given the well-documented benefits of therapy with a beta blocker, it is disturbing that this form of treatment continues to be underused, especially in high-risk groups such as older adults. Patients with a relative contraindication to beta blockers (e.g., bradyarrhythmias) should undergo a monitored trial of therapy in the hospital. The dosage should be sufficient to blunt the heart rate response to stress or exercise. Much of the impact of beta blockers in preventing mortality occurs in the first weeks; consequently, treatment should commence as soon as possible. Programs that provide physician feedback to improve adherence to guidelines should be used.

Some controversy exists regarding how long patients should be treated. The collective data from five trials that provided information on long-term follow-up of patients treated with beta blockers after infarction suggest that therapy should be continued for at least 2 to 3 years. At that time, if the beta blocker is well tolerated and there is no reason to discontinue therapy, such therapy probably should be continued in most patients (see Chapter 54).

Nitrates

Although these agents are suitable for the management of specific conditions after STEMI (such as recurrent angina) or as part of a treatment regimen for congestive heart failure, little evidence indicates that they reduce mortality over the long term when prescribed on a routine basis to all patients with infarction.

Anticoagulants

After several decades of evaluation, the weight of evidence now suggests that anticoagulants have a favorable effect on late mortality, stroke, and reinfarction in patients hospitalized with STEMI (Fig. 52-35). Given the complexities of combining long-term warfarin therapy with antiplatelet therapy, clinicians must weigh the need for warfarin based on established indications for anticoagulation, the use of other antithrombotic therapies, and the risk for bleeding.⁸³

At least three theoretical reasons exist for anticipating that anticoagulants might be beneficial in the long-term management of patients after STEMI. (1) Because the coronary occlusion responsible for STEMI is often caused by a thrombus, anticoagulants might be expected to halt progression, slow progression, or prevent the development of new thrombi elsewhere in the coronary arterial tree; (2) anticoagulants might be expected to diminish the formation of mural thrombi and resultant systemic embolization; and (3) anticoagulants might be expected to reduce the incidence of venous thrombosis and pulmonary embolization.

Alternative oral anticoagulants that have the advantage of more predictable anticoagulation with stable oral dosing, such as the oral factor Xa inhibitors, have undergone evaluation in patients with ACSs, including STEMI patients treated with background antiplatelet therapies. ATLAS ACS 2-TIMI 51 (Anti-Xa Therapy to Lower Cardiovascular Events in Addition to Standard Therapy in Subjects with Acute Coronary Syndrome–Thrombolysis in Myocardial Infarction) tested two low doses of the oral factor Xa inhibitor rivaroxaban versus placebo. Rivaroxaban at doses of both 2.5 and 5 mg twice daily significantly reduced cardiovascular death, MI, or stroke in comparison to placebo (8.9% versus 10.7%; $P = 0.008$; Fig. 52-35).²⁰⁰ Both doses also reduced stent thrombosis. The group receiving the 2.5-mg dose demonstrated a significant reduction in cardiovascular mortality

FIGURE 52-35 Outcomes with extended oral anticoagulant therapy for secondary prevention in patients with STEMI. **A**, Meta-analysis of trials of warfarin versus placebo with respect to the outcome of recurrent MI showing the potential to prevent 19 MIs per 1000 patients treated. **B**, Primary result of the ATLAS ACS 2-TIMI 51 trial, in which 15,526 patients with ACSs were randomly assigned to one of two doses of the oral factor Xa inhibitor rivaroxaban or placebo for a mean of 13 months. Rivaroxaban lowered the rate of cardiovascular death, MI, or stroke by 16%. This benefit was present in patients with STEMI ($n = 7727$), among whom a 15% reduction in the primary endpoint occurred.

(2.7% versus 4.1%; $P = 0.002$) when compared with placebo, which was not seen with 5 mg. Rivaroxaban resulted in an increase in major bleeding (2.1% versus 0.6%; $P < 0.001$) without a significant increase in fatal bleeding.

Despite similar findings in the ACS phase II studies with rivaroxaban (ATLAS ACS-TIMI 46)²⁰¹ and with another oral factor Xa inhibitor, apixaban (APPRAISE [Apixaban for Prevention of Acute Ischemic Events]),²⁰² the phase III APPRAISE-2 study, which tested apixaban versus placebo in patients following an ACS, was terminated early because of an increase in major bleeding without a significant improvement in efficacy.²⁰³ The divergent results of the ATLAS ACS 2-TIMI 51 and APPRAISE-2 studies may be related to the baseline risk of the patients in that APPRAISE-2 enrolled older patients with more comorbid conditions than the other three trials did. Consequently, these patients may have experienced competing risks and diseases not necessarily modified by anticoagulant therapy. Additionally, APPRAISE-2 included patients with a previous stroke or transient ischemic attack, and recent studies have illustrated that this group of patients may not benefit from further intensification of antithrombotic therapy. Finally, APPRAISE-2 studied higher degrees of anticoagulation than ATLAS ACS 2-TIMI 51 did.

Calcium Channel Antagonists

At present we do not recommend the routine use of calcium antagonists for secondary prevention of infarction. A possible exception is a patient who cannot tolerate a beta blocker because of adverse effects on bronchospastic lung disease but who has well-preserved left ventricular function; such patients may be candidates for a rate-slowing calcium antagonist such as diltiazem or verapamil.

Hormone Therapy (See also Chapters 42 and 77)

The decision to prescribe hormone therapy is often a complex one that involves the desire to suppress postmenopausal symptoms versus the risk for breast and endometrial cancer and vascular events. At present we recommend that hormone therapy with estrogen plus progestin not be started after STEMI and be discontinued in postmenopausal women after STEMI.

Antioxidants (See Chapter 46)

Dietary supplementation with omega-3 polyunsaturated fatty acids has been associated with a reduction in death from coronary heart disease and nonfatal reinfarction in patients within 3 months of MI. Contemporary randomized studies, however, have shown no convincing benefit in the context of guidelines-based medical therapy.^{204,205} Presently available data therefore do not support the use of antioxidant therapy for secondary prevention after STEMI.

Nonsteroidal Anti-Inflammatory Drugs

Evidence has emerged that COX-2-selective drugs and NSAIDs that have varying COX-1/COX-2 inhibitory ratios promote a prothrombotic state and that their use is associated with an increased risk for atherothrombotic events.^{206,207}

Given the increased risk for atherothrombosis related to the index STEMI event, the desire not to interfere with the beneficial pharmacologic actions of low-dose aspirin after STEMI, and reports of increased mortality and reinfarction when they are used after MI, clinicians should avoid prescribing NSAIDs to patients recovering from STEMI.¹ If NSAIDs must be prescribed for relief of pain, the lowest dose required to control symptoms should be administered for the shortest time required.²⁰⁸

FUTURE DIRECTIONS AND EMERGING THERAPIES

Although the case fatality of patients with STEMI has declined substantially, considerable opportunities for improvement remain. Of these, we emphasize four major directions: (1) evidence-based development of systems for care of patients with STEMI, (2) mitigation of reperfusion injury and impaired myocardial tissue perfusion, (3) management of cardiogenic shock after STEMI, and (4) amelioration of the adverse remodeling.

The widespread adoption of regional systems of care for patients with STEMI across diverse areas has remained challenging, and inappropriate delays to initiation of reperfusion therapy are regrettably common. Comparative effectiveness research is needed to directly test the implementation of prehospital EMS protocols, management of patients with out-of-hospital cardiac arrest, practical triage, and transfer algorithms to get patients to expert PCI services rapidly.^{10,11,80,209}

Although PCI usually restores flow through epicardial arteries, many patients do not achieve adequate nutrient flow at the myocardial level in the infarct zone because of impaired microvascular flow (Fig. 52-36; see also Fig. 52-5).⁵² Despite effective restoration of

FIGURE 52-36 Multiple mechanisms involved in the pathogenesis of no-reflow that might be targeted by appropriate therapy. ET = endothelin; TXA₂ = thromboxane A₂. (Modified from Niccoli G, Burzotta F, Galiuto L, Crea F: Myocardial no-reflow in humans. *J Am Coll Cardiol* 54:281, 2009.)

FIGURE 52-37 The demonstration that some cardiomyocytes are regenerated after birth highlights the promise and challenges of future regenerative cardiac therapies. Autologous and allogeneic sources of cells that may give rise to cardiomyocytes are under investigation. (From Parmacek MS, Epstein JA: Cardiomyocyte renewal. *N Engl J Med* 361:86, 2009.)

flow in the culprit epicardial artery, patients with impaired microvascular reperfusion have impaired survival.⁵⁰ Identification of therapies that reliably improve microvascular perfusion in the setting of primary PCI and pharmacologic reperfusion has proven challenging. The benefits of thrombus aspiration before stenting in patients undergoing primary PCI appear to be mitigated in part by improving microvascular perfusion; however, the proportion of patients with impaired microvascular flow because of distal embolization and abnormal vasomotor regulation in the distal vessels remains substantial. These abnormalities in vasomotor function are derived in part from the intense release of oxidative species and inflammatory cytokines that occurs during reperfusion of the necrotic area. This consequence of successful reperfusion, which underlies the phenomenon of reperfusion injury, can also lead to extension of myocardial injury beyond the initial ischemic zone. To date, multiple candidate interventions to reduce reperfusion injury that have appeared promising in initial studies have failed in definitive randomized trials.³⁶ Amelioration of the reperfusion injury that contributes to long-term myocardial dysfunction remains an unmet clinical need.^{39,122} Therefore processes that contribute to both microvascular obstruction²¹⁰ and reperfusion injury are potential therapeutic targets that merit ongoing investigation.

Even if reperfusion is achieved in timely fashion and microvascular obstruction is minimized, patients with STEMI inevitably lose some myocytes. When ventricular failure or severe mechanical disruption results, cardiogenic shock may ensue. Mortality from cardiogenic shock remains in excess of 40%. Improvement in the outcomes of patients in whom shock develops after STEMI remains a vexing clinical challenge.¹³¹ The disappointing results of recent trials of percutaneous mechanical support have challenged commonly held clinical assumptions.^{142,211,212} Novel therapies and strategies for the management of shock are a critical area for substantial investment in research.¹³²

In addition to the early risk for ventricular failure because of acute myocardial injury, secondary damage to the left ventricle can also

occur in the long term as a result of ventricular remodeling after STEMI.^{123,213} Treatments to minimize ventricular remodeling include the standard approaches to disruption of the RAAS and potential new therapies such as renin inhibition, reducing the amount of central nervous system generation of aldosterone, enhancing the synthesis of endothelial nitric oxide synthase, modulating beta-adrenergic signaling, and minimizing the processes that lead to cardiac apoptosis.^{123,213} Novel approaches using biologic and mechanical interventions to improve ventricular structure are under investigation.²¹⁴⁻²¹⁶ Moreover, myocytes are capable of entering the cell cycle and dividing (see Chapter 30).²¹⁷ The burgeoning field of cardiac regenerative medicine holds promise to support amelioration of the adverse ventricular remodeling by using both endogenous and exogenous sources of cells that give rise to myocytes (Fig. 52-37).²¹⁸

ACKNOWLEDGMENT

The authors wish to acknowledge the previous contributions of Dr. Elliott M. Antman, which have laid the foundation for this chapter.

GUIDELINES

Management of Patients with ST-Elevation Myocardial Infarction

Stephen D. Wiviott

The American College of Cardiology Foundation/American Heart Association (ACCF/AHA) updated guidelines for the diagnosis and management of patients with ST-elevation myocardial infarction (STEMI) in 2013.¹ As with other ACCF/AHA guidelines, indications for interventions are classified into the following four groups:

Class I—For generally accepted indications

Class IIa—When indications are controversial but the weight of evidence is supportive

Class IIb—When usefulness or efficacy is less well established

Class III—When there is consensus against the usefulness of the intervention

The guidelines use a convention for rating the level of evidence (LOE) on which recommendations have been based, as follows:

Level A—Derived from data from multiple randomized clinical trials
Level B—Derived from a single randomized trial or nonrandomized studies

Level C—Based on the consensus opinion of experts or standard of care

DEFINITION AND DIAGNOSIS

STEMI is defined by symptoms of myocardial ischemia associated with persistent electrocardiographic evidence of ST elevation and subsequent elevation of biologic markers of myocardial necrosis. According to the universal definition of myocardial infarction (MI), ST elevation in the absence of either left bundle branch block (LBBB) or left ventricular (LV) hypertrophy is defined as new ST elevation of at least 2 mm in men or 1.5 mm in women in at least two contiguous leads.² New or presumably new LBBB at initial evaluation should not be considered diagnostic of MI. Interpretation of the electrocardiogram (ECG) may be obscured by previous LBBB, paced rhythm, LV hypertrophy, or Brugada syndrome.

ONSET OF MYOCARDIAL INFARCTION

Time until treatment is paramount in the management of STEMI, and early recognition, transport, and treatment can improve outcomes in patients with this syndrome.

Patient-Related Delays and Initial Treatment

Time delays in seeking care tend to be longer in women, blacks, and older adults. Reasons for delays may include failure to recognize symptoms, uncertainty of the severity of symptoms, and lack of understanding of the importance of rapid treatment. The STEMI guidelines emphasize the importance of health care providers making anticipatory plans, including the need to activate the emergency medical service (EMS) system and institution of early aspirin use. Patients should learn warning systems, develop a survival plan, and discuss risk reduction with their physicians to improve potential outcomes.

Mode of Transport to the Hospital

Patients with ischemic symptoms should be transported to the hospital by ambulance rather than by friends or family. Ambulance transport is associated with earlier recognition of STEMI, faster times to

reperfusion, and lower mortality. The benefits of ambulance transport are increased by prehospital communication of the diagnosis of STEMI and by preference for transfer to hospitals capable of performing percutaneous coronary intervention (PCI).

Community Preparedness and Systems Goals for Reperfusion Therapy

Time until appropriate reperfusion therapy is one key to the treatment of STEMI. Goals of achieving rapid reperfusion should be facilitated by community-based systems designed for the rapid management of patients with STEMI. **Figure 52G-1** outlines the major strategies and decision points for the management of patients with STEMI.

Class I recommendations include the following:

- Communities should create and maintain regional systems of STEMI care that includes assessment and quality improvement of EMS and hospital-based activities (Level of evidence: B).
- A 12-lead ECG should be performed by EMS personnel at the site of first medical contact (FMC) in patients with symptoms consistent with STEMI (Level of evidence: B).
- Reperfusion therapy should be administered to all eligible patients with STEMI in whom the onset of symptoms began within the previous 12 hours (Level of evidence: A).
- Primary PCI is the recommended method of reperfusion when experienced operators can perform it within timely fashion (Level of evidence: A).
- EMS transport directly to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI, with an ideal FMC-to-device time goal of 90 minutes or less (Level of evidence: B).
- Immediate transfer to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI who initially arrive at or are transported to a non-PCI-capable hospital, with an FMC-to-device time goal of 12 minutes or less (Level of evidence: B).
- Without contraindications, fibrinolytic therapy should be administered to patients with STEMI at non-PCI-capable hospitals when the anticipated FMC-to-device time at a PCI-capable hospital exceeds 120 minutes because of unavoidable delays (Level of evidence: B).
- When fibrinolytic therapy is indicated or chosen as the primary reperfusion strategy, it should be administered within 30 minutes of hospital arrival (Level of evidence: B).

When selecting reperfusion therapy, the provider must consider several features in relation to these recommendations, including time from the onset of symptoms, risk for STEMI-related complications, risk for bleeding, presence of heart failure or shock, and time required for the administration of fibrinolytics versus the time needed for transfer to a PCI-capable hospital. Patients best suited for transfer to PCI-capable hospitals include those with congestive heart failure (CHF) or shock, high bleeding risk, longer than 3 to 4 hours after onset of symptoms, and short transfer times to PCI-capable hospitals. Those best suited for initial fibrinolytic therapy include patients with low bleeding risk, very early after the onset of symptoms, and longer delays until the performance of PCI.

Relationship Between Sudden Cardiac Death and ST-Elevation Myocardial Infarction

STEMI is inexorably linked to sudden cardiac death. Indeed, some 70% of deaths attributable to coronary heart disease occur with out-of-hospital arrest. Comprehensive management of out-of-hospital arrest extends beyond the scope of this chapter, but the STEMI guidelines offer key recommendations for the evaluation and management of patients with STEMI and out-of-hospital cardiac arrest, including the following class I recommendations:

- Therapeutic hypothermia should be started as soon as possible in comatose patients with STEMI and out-of-hospital cardiac arrest caused by ventricular fibrillation or pulseless ventricular tachycardia, including patients who undergo primary PCI (Level of evidence: B).

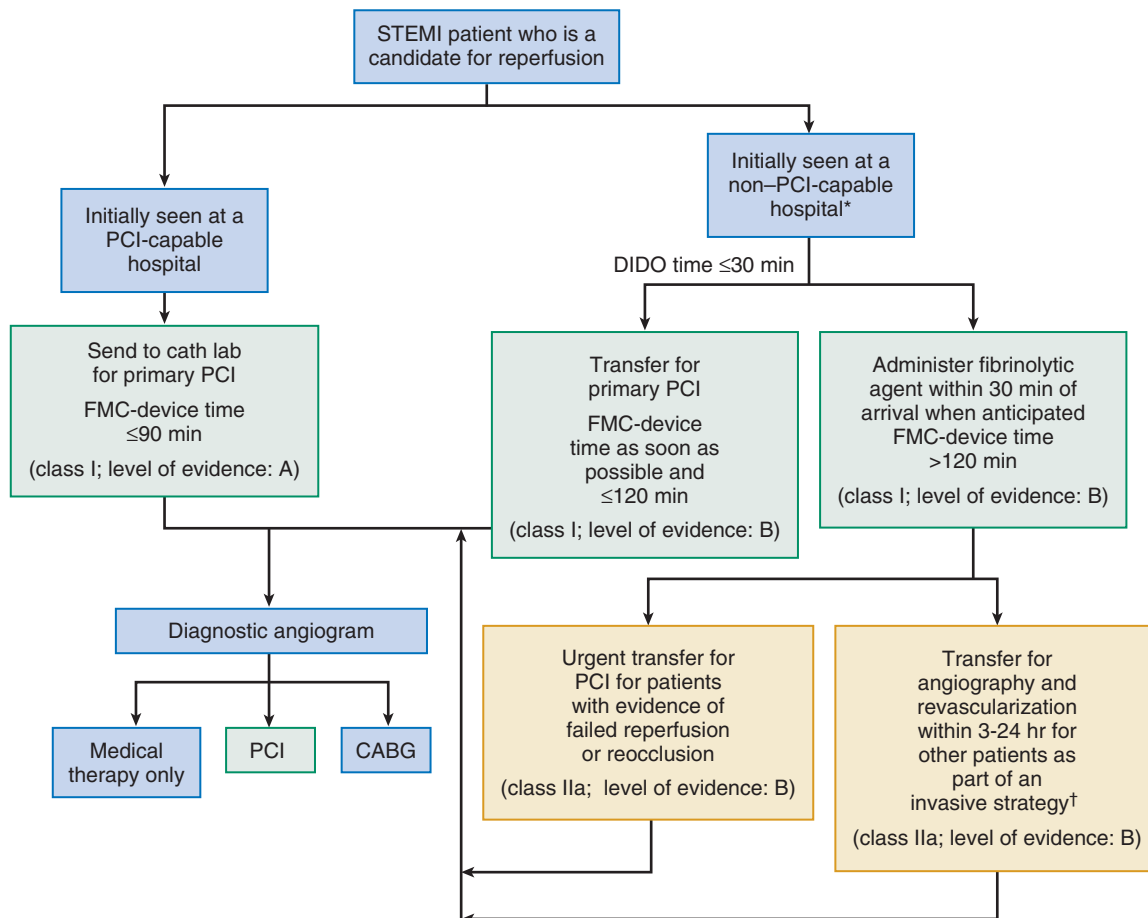

FIGURE 52G-1 Reperfusion therapy for patients with STEMI. The **bold arrows** and **boxes** are the preferred strategies. Performance of PCI is dictated by an anatomically appropriate culprit stenosis. *Patients with cardiogenic shock or severe heart failure initially seen at a non-PCI-capable hospital should be transferred for cardiac catheterization and revascularization as soon as possible, irrespective of the delay in time after the onset of MI (class I; Level of evidence: B). †Angiography and revascularization should not be performed within the first 2 to 3 hours after the administration of fibrinolytic therapy. DIDO = door in–door out. (Modified from O’Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 127:e362, 2013.)

- Immediate angiography and PCI, when indicated, should be performed in resuscitated patients with out-of-hospital cardiac arrest whose initial ECG shows STEMI (Level of evidence: B).

REPERFUSION AT A HOSPITAL CAPABLE OF PERFORMING PERCUTANEOUS CORONARY INTERVENTIONS

The 2013 STEMI guidelines are divided into sections describing appropriate care at PCI-capable hospitals versus non-PCI-capable hospitals.¹

Primary Percutaneous Coronary Intervention

Primary PCI is generally preferable to fibrinolytic therapy when time until treatment is short and the patient arrives at a high-volume, well-equipped center with experienced operators and support staff. When compared with fibrinolysis, primary PCI produces higher rates of TIMI (Thrombolysis in Myocardial Infarction) grade 3 flow and patent infarct-related arteries and lower rates of recurrent ischemia, urgent revascularization, recurrent MI, and death. Primary PCI, when successful, also results in early hospital discharge and return to activities. Such improvements are less or absent in low-volume centers or

with low-volume operators. Potential adverse effects of primary PCI include arterial access site complications and contrast agent- and antithrombotic-related complications. A summary of the recommendations is encapsulated in **Table 52G-1**.

Procedural Considerations

The 2013 STEMI guidelines offer a class IIa recommendation for manual aspiration thrombectomy in patients undergoing primary PCI, although subsequent trial data do not show that this procedure reduces 30-day mortality in patients with STEMI.³ Class I indications are given for the use of intracoronary stents at the time of primary PCI (Level of evidence: A). Either drug-eluting stents (DESs) or bare metal stents (BMSs) can be used, but when patients are anticipated to be at high bleeding risk or are probably not compliant with dual antiplatelet therapy (DAPT) for other reasons, a class I indication is given for the use of BMSs and a class III indication for DESs—because of the risk for delayed stent thrombosis in DESs with premature discontinuation of DAPT. **Table 52G-2** summarizes the adjunctive antithrombotic therapy for primary PCI, including antiplatelet therapy and anticoagulant therapy.

For antiplatelet therapy, class I recommendations include aspirin and P2Y₁₂ receptor antagonists.

Aspirin

- Aspirin (162 to 325 mg) should be given before primary PCI (Level of evidence: B).

TABLE 52G-1 Primary Percutaneous Coronary Intervention for ST-Elevation Myocardial Infarction

	COR	LEVEL OF EVIDENCE
Ischemic symptoms <12 hr	I	A
Ischemic symptoms <12 hr and contraindications to fibrinolytic therapy irrespective of delay in time after FMC	I	B
Cardiogenic shock or acute severe HF irrespective of delay in time after the onset of MI	I	B
Evidence of ongoing ischemia 12-24 hr after the onset of symptoms	IIa	B
PCI on a noninfarct artery at the time of primary PCI in patients without hemodynamic compromise	III: Harm	B

COR = class of recommendation; HF = heart failure.

	COR	LEVEL OF EVIDENCE
Anticoagulant Therapy		
• UFH		
• With a GP IIb/IIIa receptor antagonist planned: 50- to 70-unit/kg IV bolus to achieve therapeutic ACT [‡]	I	C
• With no GP IIb/IIIa receptor antagonist planned: 70- to 100-unit/kg bolus to achieve a therapeutic ACT [‡]	I	C
• Bivalirudin: 0.75-mg/kg IV bolus, then 1.75-mg/kg/hr infusion with or without previous treatment with UFH. An additional bolus of 0.3 mg/kg may be given if needed	I	B
• Reduce the infusion to 1 mg/kg/hr with estimated an CrCl <30 mL/min		
• Preferred over UFH with a GP IIb/IIIa receptor antagonist in patients at high risk for bleeding	IIa	B
• Fondaparinux: not recommended as the sole anticoagulant for primary PCI	III: Harm	B

*The recommended maintenance dose of aspirin to be used with ticagrelor is 81 mg daily.

[†]Balloon angioplasty without stent placement may be used in selected patients. It might be reasonable to provide P2Y₁₂ inhibitor therapy to patients with STEMI undergoing balloon angioplasty alone according to the recommendations listed for BMSs (Level of evidence: C).

[‡]The recommended ACT with planned GP IIb/IIIa receptor antagonist treatment is 200 to 250 seconds.

[§]The recommended ACT with no planned GP IIb/IIIa receptor antagonist treatment is 250 to 300 seconds (HemoTec device) or 300 to 350 seconds (Hemochron device). ACT = activated clotting time; rCrI = creatinine clearance; COR = class of recommendation; GP = glycoprotein; IV = intravenous.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 127:e362, 2013.

- After PCI, aspirin should be continued indefinitely (Level of evidence: B). *Note:* An 81-mg dose of aspirin is recommended for maintenance (class IIa; Level of evidence: B) instead of higher doses.

P2Y₁₂ Antagonists

- A loading dose of a P2Y₁₂ receptor inhibitor should be given as early as possible or at the time of primary PCI in patients with STEMI (Level of evidence: B), with options including clopidogrel, 600 mg (Level of evidence: B); prasugrel, 60 mg (Level of evidence: B); or ticagrelor, 180 mg (Level of evidence: B).
- A P2Y₁₂ antagonist should be prescribed for 1 year to patients with STEMI after primary PCI when they receive a stent. Options include clopidogrel, 75 mg daily (Level of evidence: B); prasugrel, 10 mg daily (Level of evidence: B); or ticagrelor, 90 mg twice daily (Level of evidence: B). *Note:* Prasugrel should not be used (class III, Level of evidence: B) in patients with a history of transient ischemic attack (TIA) or stroke.
- For anticoagulant therapy, key recommendations include supportive anticoagulation with unfractionated heparin (UFH), with dosing being based on the activated clotting time (class I, Level of evidence: C), or with bivalirudin in patients who have not been treated previously with UFH (class I; Level of evidence: B). In patients with a high risk for bleeding, bivalirudin is generally recommended instead of heparin plus a glycoprotein IIb/IIIa receptor antagonist (class IIa; Level of evidence: B), and fondaparinux should not be used as the sole anticoagulant (class III; Level of evidence: B).

REPERFUSION AT A HOSPITAL NOT CAPABLE OF PERFORMING PERCUTANEOUS CORONARY INTERVENTIONS

The guidelines categorize the management of patients at a non-PCI-capable hospital into three phases: fibrinolytic therapy, assessment of patency, and transfer to a PCI-capable hospital.

Fibrinolytic Therapy When the Delay Anticipated Is Within 120 Minutes

The key recommendations for the indications for fibrinolytic therapy with a delay of longer than 120 minutes from FMC to primary PCI are summarized in [Table 52G-3](#).

TABLE 52G-3 Indications for Fibrinolytic Therapy When the Delay from First Medical Contact to Primary Percutaneous Intervention Is Longer than 120 Minutes

	COR	LEVEL OF EVIDENCE

Evidence of ongoing ischemia 12-24 hr after the onset of symptoms and a large area of myocardium at risk or hemodynamic instability	IIa	C
ST depression except if true posterior (inferobasal) MI is suspected or when associated with ST-elevation in lead aVR	III: Harm	B

COR = class of recommendation.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 127:e362, 2013.

The 2013 STEMI guidelines recommend fibrin-specific agents over non-fibrin-specific agents when available.¹ Fibrin-specific regimens include single-bolus tenecteplase (TNK tissue plasminogen activator [t-PA]), double-bolus reteplase (r-PA), or infusion of alteplase (t-PA). Streptokinase administered over a 30- to 60-minute period is the only nonspecific agent recommended. The choice of fibrinolytic agent depends on a risk-benefit analysis that integrates time from the onset of symptoms, clinical features, comorbid conditions, delay until performance of PCI, and potential contraindications ([Table 52G-4](#)). [Table 52G-5](#) summarizes antithrombotic therapy for STEMI treated with fibrinolytic therapy.

Antiplatelet Therapy

- A loading dose of aspirin (162 to 325 mg) and clopidogrel (300 mg in patients ≤75 years of age; 75 mg in patients >75 years of age) should be administered with fibrinolytic therapy (class I; Level of evidence: A).
- Aspirin should be continued indefinitely, and clopidogrel should be continued for at least 14 days and up to 1 year (class I; Level of evidence: A). *Note:* A dose of 81 mg of aspirin is preferred instead of higher maintenance dosing (class IIa; Level of evidence: B).

Anticoagulant Therapy

Patients with STEMI treated with fibrinolytic therapy for reperfusion should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of hospitalization, up to 8 days or until revascularization is performed (class I, Level of evidence: A). Acceptable regimens include UFH for up to 48 hours (Level of evidence: C), enoxaparin for up to 8 days (Level of evidence: A), or fondaparinux for up to 8 days (Level of evidence: B).

Assessment of Reperfusion after Fibrinolysis

Sudden and complete relief of chest pain, coupled with greater than 70% ST resolution, is highly correlated with normal coronary artery blood flow in the infarct-related artery and suggests reperfusion.

TABLE 52G-4 Contraindications to Fibrinolytic Therapy for ST-Elevation Myocardial Infarction

Absolute Contraindications

Any previous intracranial hemorrhage
Known structural cerebral vascular lesion
Known malignant intracranial neoplasm
Ischemic stroke within 3 months (except ischemic stroke within 4.5 hours)
Suspected aortic dissection
Active bleeding or bleeding diathesis
Significant closed-head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Severe uncontrolled hypertension (not responsive to emergency therapy)
For streptokinase, previous treatment within 6 months

Relative Contraindications

History of chronic, severe, poorly controlled hypertension
Significant hypertension at initial evaluation (systolic blood pressure >180 mm Hg, diastolic blood pressure >110 mm Hg)
History of ischemic stroke >3 months
Dementia
Known intracranial pathology not covered in Absolute Contraindications
Traumatic or prolonged cardiopulmonary resuscitation (>10 minutes)
Major surgery within 3 weeks
Recent internal bleeding (within 2-4 weeks)
Noncompressible vascular puncture
Pregnancy
Active peptic ulcer
Oral anticoagulant therapy

Transfer to a Hospital Capable of Performing Percutaneous Coronary Interventions after Fibrinolytic Therapy

Key recommendations for transfer to a PCI-capable hospital for angiography are summarized in [Table 52G-6](#). The only class I indication for immediate transfer in the 2013 STEMI guidelines is for patients with severe heart failure or cardiogenic shock, but the general recommendation is for all patients who have failed reperfusion or suffered reocclusion (class IIa; Level of evidence: B) to be transferred urgently and for stable patients to be transferred routinely (class IIa; Level of evidence: B).

DELAYED INVASIVE MANAGEMENT

Coronary Angiography and Percutaneous Coronary Intervention in Patients Initially Managed with Fibrinolytic Therapy or in Those with No Reperfusion

Key recommendations for indications for coronary angiography and PCI are summarized in [Table 52G-7](#). PCI should be performed when angiography identifies significant stenosis in the infarct-related arteries. Class I indications relate to high-risk clinical features (cardiogenic shock, severe CHF), recurrent spontaneous or provoked ischemia, or high-risk features on noninvasive testing. PCI on non-infarct-related arteries should be based on spontaneous symptoms (class I; Level of evidence: C) or high-risk features on noninvasive testing (class IIa; Level of evidence: B) suggestive of ischemia in the territory of the non-infarct-related artery. One study published after the guidelines suggested a benefit of PCI on non-infarct-related arteries.⁴

Adjunctive Antithrombotic Agents to Support Delayed Percutaneous Coronary Intervention

Adjunctive antiplatelet therapy and anticoagulant therapy to support delayed PCI are summarized in [Table 52G-8](#). Antiplatelet and anticoagulant therapies in patients in whom PCI is delayed are similar to those in patients who undergo PCI early, but the timing and dosing of P2Y₁₂ antagonists differ depending on the time interval and type of fibrinolytic agent given. Notably, a loading dose of 300 mg of clopidogrel should be administered (if not already given with fibrinolysis) within 24 hours of PCI and a 600-mg loading dose

Maintenance Doses and Duration of Therapy		
<i>DES placed: Continue therapy for at least 1 yr with</i>		
• Clopidogrel: 75 mg daily	I	C
• Prasugrel: 10 mg daily	IIa	B
<i>BMS* placed: Continue therapy for at least 30 days and up to 1 yr with</i>		
• Clopidogrel: 75 mg daily	I	C
• Prasugrel: 10 mg daily	IIa	B
Anticoagulant Therapy		
• Continue UFH throughout PCI while administering additional IV boluses as needed to maintain a therapeutic ACT, depending on use of a GP IIb/IIIa receptor antagonist [†]	I	C
• Continue enoxaparin throughout PCI:	I	B
• No additional drug if the last dose was given within the previous 8 hr		
• 0.3-mg/kg IV bolus if the last dose was given 8-12 hr earlier		
• Fondaparinux:	III: Harm	C
• As sole anticoagulant for PCI		

*Balloon angioplasty without stent placement may be used in selected patients. It might be reasonable to provide P2Y₁₂ inhibitor therapy to patients with STEMI undergoing balloon angioplasty after fibrinolysis alone according to the recommendations listed for BMSs (Level of evidence: C).

[†]The recommended ACT with no planned GP IIb/IIIa receptor antagonist treatment is 250 to 300 seconds (HemoTec device) or 300 to 350 seconds (Hemochron device).

ACT = activated clotting time; COR = class of recommendation; IV = intravenous.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 127:e362, 2013.

thereafter. Prasugrel should be used at standard dosing, but not within 48 hours of fibrinolytic therapy. Anticoagulant therapy can consist of UFH (class I; Level of evidence: C) or enoxaparin (class I; Level of evidence: B), but fondaparinux should not be used as a stand-alone anticoagulant (class III; Level of evidence: B).

CORONARY ARTERY BYPASS GRAFT SURGERY

The 2013 STEMI guidelines accord coronary artery bypass grafting (CABG) a relatively limited role in the management of patients with STEMI. The only class I indications for CABG in patients with STEMI include the management of those whose coronary anatomy is not amenable to PCI; those who have ongoing or recurrent ischemia, shock, severe heart failure, or other high-risk features (Level of

evidence: B); and patients at the time of operative repair of mechanical defects, such as a ventricular septal defect (Level of evidence: B).

In general, aspirin should be continued throughout the pre-CABG and peri-CABG periods. With the understanding that CABG is often urgent in the setting of STEMI, clopidogrel or ticagrelor should be discontinued for at least 24 hours when possible. In stable settings, clopidogrel and ticagrelor should be stopped for 5 days and prasugrel stopped for 7 days before CABG, but earlier surgery may be considered if the benefits outweigh the risks (class IIb).

ROUTINE MEDICAL THERAPIES

Pharmacologic management of STEMI is covered in the chapter accompanying these guidelines. **Table 52G-9** summarizes the indications and cautions for routine medical therapies in patients following STEMI, as based on the 2013 guidelines.

TABLE 52G-9 Indications and Cautions for Adjunctive Medical Therapies for Patients with ST-Elevation Myocardial Infarction

Beta-adrenergic receptor–blocking agents	Oral: All patients without contraindication IV: Patients with refractory hypertension or ongoing ischemia without contraindication	Signs of CHF Low-output state Increased risk for cardiogenic shock Prolonged first-degree or high-grade atrioventricular block Reactive airways disease
Angiotensin-converting enzyme (ACE) inhibitors	Anterior MI and EF ≤ 0.40 or CHF All patients without contraindication	Hypotension Renal failure Hyperkalemia
Angiotensin receptor–blocking agents (ARBs)	Intolerant of ACE inhibitors	Hypotension Renal failure Hyperkalemia
Statins	All patients without contraindications	With drugs metabolized via CYP3A4, fibrates Monitor for myopathy, hepatotoxicity Adjust dose for lipid targets
Nitroglycerin	Ongoing chest pain Hypertension and CHF	Suspected right ventricular infarction SBP < 90 (or 30 mm Hg below baseline) Recent use of a type 5 PDE inhibitor
Oxygen	Clinically significant hypoxemia ($SpO_2 < 90$) CHF Dyspnea	Chronic obstructive pulmonary disease and CO_2 retention
Morphine	Pain Anxiety Pulmonary edema	Lethargic or moribund patient Hypotension Bradycardia Known hypersensitivity

EF = ejection fraction; PDE = phosphodiesterase; SBP = systolic blood pressure.

RISK ASSESSMENT AFTER STELEVATION MYOCARDIAL INFARCTION

Post-STEMI risk assessment allows the clinician's initial impression to be updated based on data occurring during the hospital stay, such as successful reperfusion, angiographic parameters, clinical heart failure or arrhythmia, and ventricular function; noninvasive testing may be helpful. Testing for the presence of residual ischemia may be helpful in patients following STEMI. The only class I recommendation is to use noninvasive testing for ischemia before discharge in patients who did not undergo angiography and who did not have high-risk features for which coronary angiography would be warranted. (Level of evidence: B.)

Because LV function strongly predicts outcome in patients with STEMI, it is recommended with a class I indication that all patients with STEMI undergo measurement of their LV ejection fraction (LVEF). Echocardiography is the most commonly used modality and can assess for mechanical complications, in addition to ventricular function. In general, this assessment can be performed on day 2 to 3 following MI, and in patients with significant ventricular dysfunction it should be repeated more than 40 days after MI to evaluate the potential need for an implantable cardioverter-defibrillator (ICD).

In the absence of a reversible cause, late (defined as > 48 hours after MI) in-hospital sustained ventricular tachycardia or ventricular fibrillation is an indication (class I; level of evidence: B) for ICD therapy. In patients who do not have an indication for ICD therapy based on late life-threatening arrhythmias, evaluation of LVEF to determine the need for an ICD for primary prevention of sudden cardiac death should be performed with sufficient time to allow any LV stunning to resolve. Based on the 2013 STEMI guidelines, patients with an LVEF of 0.40 or lower should have echocardiography repeated more than 40 days after MI. If the LVEF remains 0.35 or lower and the patient has a class II or III New York Heart Association classification of CHF or an LVEF of 0.30 or lower independent of symptoms, an ICD is indicated.

POSTHOSPITALIZATION PLAN OF CARE

Transition from hospital to outpatient care requires a careful discharge and follow-up plan. Class I indications for posthospital care planning include the following:

- Posthospital systems of care designed to prevent hospital readmission should be used to facilitate the transition to effective, coordinated outpatient care for all patients with STEMI. (Level of evidence: B.)
- Exercise-based cardiac rehabilitation/secondary prevention programs are recommended for patients with STEMI. (Level of evidence: B.)
- A clear, detailed, evidence-based plan of care that promotes adherence to medication, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with interventions for secondary prevention should be provided to patients with STEMI. (Level of evidence: C.)
- Encouragement and advice to stop smoking and to avoid secondhand smoke should be provided to patients with STEMI. (Level of evidence: A.)

Key components in the plan of care should include medications, physical activity/rehabilitation, risk factor modification, lifestyle interventions, attention to management of comorbid conditions and psychosocial factors, provider follow-up, patient and family education, and socioeconomic factors.

BACKGROUND

Definitions

Ischemic heart disease may be manifested clinically as either chronic stable angina (see Chapter 54) or an acute coronary syndrome (ACS). The latter, in turn, can be subdivided into ST-segment elevation myocardial infarction (STEMI), non-ST-segment elevation myocardial infarction (NSTEMI), or unstable angina (UA) (Fig. 53-1). Chapters 51 and 52 discuss STEMI in detail. Because NSTEMI and UA are indistinguishable at initial evaluation and the entity of UA is receding as the sensitivity of biomarkers of myocardial injury increases, they are often described together as NSTEMI-ACS and are discussed together in this chapter.

Features that help differentiate ACS from stable angina are (1) onset of symptoms at rest (or with minimal exertion) and lasting longer than 10 minutes unless treated promptly; (2) severe, oppressive pressure or chest discomfort; and (3) an accelerating pattern of symptoms that develop more frequently, occur with greater severity, or awaken the patient from sleep. Symptoms alone do not suffice to distinguish the three types of ACS from one another. Patients without persistent (>20 minutes) ST-segment elevation in two or more contiguous leads but with biomarker evidence of myocardial necrosis are classified as having NSTEMI, whereas in patients without such evidence of myocardial necrosis, UA is diagnosed—a condition generally carrying a better prognosis.

Epidemiology

Globally, ischemic heart disease remains the number one cause of mortality; it was responsible for 7 million of the 53 million deaths reported in 2010.¹ ACS, the acute manifestation of ischemic heart disease, accounted for approximately 1.1 million discharges in the United States in 2009,² with approximately twice this number in Europe. The annual number of hospital discharges for ACS in developed countries has declined slowly over the past two decades, accompanied by an increase in nations with developing economies (see Chapter 1).³ In the United States, three recent trends have changed the frequency distribution of the types of ACS: (1) wider use of primary preventive therapies (aspirin, statins, smoking cessation) appears to have resulted in fewer cases of STEMI⁴; (2) aging of the U.S. population, with higher rates of diabetes and chronic kidney disease (CKD), have increased the incidence of NSTEMI-ACS⁵; and (3) the use of more sensitive assays for myocardial necrosis (i.e., cardiac-specific troponin [cTn]) has shifted the classification of NSTEMI-ACS

away from UA toward NSTEMI⁵ (Fig. 53-2; also see Fig. 51-2A). Overall, the age- and sex-adjusted incidence rates of NSTEMI have grown slowly since 1999.⁴

PATHOPHYSIOLOGY

The pathogenesis of NSTEMI-ACS involves four processes: (1) rupture of unstable atheromatous plaque, (2) coronary arterial vasoconstriction, (3) imbalance between the supply and demand of the myocardium for oxygen, and (4) gradual intraluminal narrowing of an epicardial coronary artery because of progressive atherosclerosis or poststenotic restenosis. These processes are not mutually exclusive and can occur simultaneously in any combination.

Plaque rupture or erosion leads to the formation of superimposed thrombus (typically nonocclusive in NSTEMI-ACS) along with subsequent impaired myocardial perfusion, which if persistent, leads to myocardial necrosis. Inflammation of the arterial wall and the action of metalloproteinases produced by inflammatory cells in degrading the fibrous wall of plaque contribute to their instability (see Chapter 41).

Vasoconstriction causing dynamic obstruction of coronary arterial flow may result from spasm of the epicardial coronary arteries (Prinzmetal angina, see below)—constriction of small, intramural, muscular coronary arteries resulting in increased coronary vascular resistance. This constriction may result from vasoconstrictors released by platelets, endothelial dysfunction (cardiac syndrome X; see Chapter 77), or adrenergic stimuli (e.g., the “fight-or-flight” response, cold, cocaine, or amphetamines [Chapter 68]). More than one of these mechanisms may be present simultaneously. Insufficient myocardial O₂ supply may also occur in patients with severe anemia and hypotension. When an increase in myocardial O₂ demand (e.g., tachycardia, fever, thyrotoxicosis) occurs in a patient with fixed narrowing of an epicardial coronary artery, secondary NSTEMI-ACS may develop.

Activation of the coagulation cascade and platelets plays a central role (described in detail in Chapter 82) in the formation of thrombus following plaque rupture/erosion. The first step in thrombus formation is vascular injury or endothelial dysfunction, which causes *adhesion* of platelets to the arterial wall via binding of platelet glycoprotein (GP) Ib to subendothelial von Willebrand factor. Exposure of platelets to subendothelial collagen and/or circulating thrombin causes platelet *activation* (Fig. 53-3), which induces platelets to change shape and results in degranulation with release of adenosine diphosphate

FIGURE 53-1 Spectrum of ACSs. ECG = electrocardiogram. (Modified from Hamm CW, Bassand JP, Agewall S, et al: ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation: The Task Force for the Management of Acute Coronary Syndromes (ACS) in Patients Presenting Without Persistent ST-Segment Elevation of the European Society of Cardiology (ESC). *Eur Heart J* 32:2999, 2011.)

TRENDS OF STEMI AND NSTEMI IN NRMI REGISTRY (1990–2006)

FIGURE 53-2 Trends of STEMI and NSTEMI in National Registry of Myocardial Infarction (NRMI) from 1990 to 2006. The proportion of patients with STEMI or NSTEMI and the proportion of patients in whom a troponin assay was used to diagnose AMI are shown. (From Rogers WJ, Frederick PD, Stoehr E, et al: Trends in presenting characteristics and hospital mortality among patients with ST elevation and non-ST elevation myocardial infarction in the National Registry of Myocardial Infarction from 1990 to 2006. *Am Heart J* 156:1026, 2008.) (Also see Figure 51-2.)

FIGURE 53-3 Platelet activation mechanisms and sites of blockade of antiplatelet therapies. Platelet activation is initiated by soluble agonists such as thrombin, TxA₂, 5-HT (hydroxytryptamine), ADP (via P2Y₁ and P2Y₁₂), and ATP and by adhesive ligands such as collagen and von Willebrand factor. Consequently, dense granule secretion of platelet agonists and secretion of TxA₂ lead to amplification of platelet activation, which causes a conformational change in the GPIIb/IIIa receptor that leads it to bind to fibrinogen and results in platelet aggregation. The P2Y₁₂ receptor plays a major role in the amplification of platelet activation. ASA = acetylsalicylic acid; ATP = adenosine 5'-triphosphate; cAMP = cyclic adenosine monophosphate; COX-1 = cyclooxygenase-1; PAR = protease receptor protein; TP = human thromboxane A₂ receptor; TRA = thrombin receptor antagonist; X = sites of action of antiplatelet agents. (From Braunwald E: *Unstable angina and non-ST elevation myocardial infarction*. *Am J Respir Crit Care Med* 185:924, 2012. Modified from Storey RF: *Biology and pharmacology of the platelet P2Y₁₂ receptor*. *Curr Pharm Des* 12:1255, 2006. From Wal-lentin L: *P2Y₁₂ inhibitors: Differences in properties and mechanisms of action and potential consequences for clinical use*. *Eur Heart J* 30:1964, 2009.)

(ADP) and thromboxane A₂ (TxA₂)—which in turn causes further platelet activation and expression of platelet glycoprotein GPIIb/IIIa.

In parallel, tissue factor expressed within the lipid-rich core of atherosclerotic plaque, when exposed to circulating blood, activates the coagulation cascade. A complex of tissue factor and coagulation

factors VIIa and Va leads to the formation of activated factor X (factor Xa), which in turn amplifies the production of activated factor IIa (thrombin). The cascade proceeds with thrombin-induced conversion of fibrinogen to fibrin. The platelet and coagulation systems converge in that thrombin is also a potent platelet activator. Platelet

GP IIb/IIIa binds circulating fibrinogen, thereby causing platelet aggregation and ultimately producing a platelet-fibrin thrombus, portions of which may embolize distally and cause myocardial necrosis.

The central role of coronary artery thrombosis in the pathogenesis of NSTEMI-ACS is supported by (1) autopsy findings of thrombi in the coronary arteries typically localized to a ruptured or eroded atherosclerotic plaque; (2) a high incidence of thrombotic lesions in coronary atherectomy specimens in patients with NSTEMI-ACS in comparison to those with stable angina; (3) observations of plaque ulceration and/or irregularities in the fibrous cap of atherosclerotic plaque consistent with plaque rupture and thrombus formation as visualized by coronary angiography, intravascular ultrasound (IVUS), optical coherence tomography (OCT), or computed tomographic angiography (CTA); (4) elevation of serum markers of platelet activity, thrombin generation, and fibrin formation; and (5) improvement in clinical outcome with antiplatelet and anticoagulant treatment.

CLINICAL ASSESSMENT

History and Physical Examination

NSTEMI-ACS resulting from atherosclerosis is relatively uncommon in men younger than 40 years and women younger than 50 years, but the incidence rises steadily thereafter. Although NSTEMI-ACS may be the initial manifestation of coronary heart disease (CHD), most patients have preceding stable angina or myocardial infarction (MI). Patients with ACS more frequently have traditional risk factors for CHD (see Chapter 42) than do normal subjects or those with nonischemic chest pain. Although coronary risk factors can be used to assess risk in populations, they are less helpful in the assessment of individual patients.

The initial symptom is typically described as pressure, heaviness, or frank pain beneath the sternum (see Chapter 50), and it resembles stable exertional angina—but is usually more intense and lasts longer (>20 minutes). Associated radiation to the ulnar aspect of the proximal part of the left arm, either shoulder, the neck, or the jaw may occur, but symptoms may be present anywhere between the ear and epigastrium.⁶ Symptoms such as diaphoresis, nausea, abdominal pain, dyspnea, and syncope may accompany the pain. Features that support the diagnosis include exacerbation of symptoms by physical exertion; precipitation by severe anemia, infection, inflammation, fever, or metabolic or endocrinologic (e.g., thyroid) disorders; and importantly, relief with rest or nitroglycerin. Atypical manifestations, such as dyspnea without chest discomfort, pain limited to the epigastrium, or indigestion, represent “anginal equivalents.” These atypical findings are more prevalent in women, older adults, and patients with diabetes, CKD, or dementia and can lead to underrecognition, undertreatment, and worse outcomes. Chest pain that is pleuritic or described as stabbing is generally noncardiac in origin.

The clinical manifestations may be sudden, with severe, new-onset symptoms occurring during minimal exertion (Canadian Cardiovascular Society class⁷ [CCSC] III) or at rest (CCSC IV), an accelerating pattern of angina (more frequent, more intense, longer lasting), or angina occurring shortly after a completed MI.⁸

Physical Examination

Findings on physical examination may be normal, although patients with large territories of myocardial ischemia may have audible third and/or fourth heart sounds. Rarely, hypotension, pale cool skin, sinus tachycardia, or frank cardiogenic shock can occur; these findings are far more common with STEMI than with NSTEMI-ACS. The examination can also be important in that potential precipitating causes of ACS can be identified, such as fever, resistant hypertension, tachycardia, profound bradycardia, thyroid disease, or gastrointestinal bleeding. Finally, findings on physical examination such as pulse deficits, tachypnea, and tachycardia in the presence of clear lung fields and pulsus paradoxus with jugular venous distention may lead to alternative life-threatening diagnoses such as aortic dissection, pulmonary embolism, or cardiac tamponade.

Electrocardiography

The most common abnormalities on the 12-lead electrocardiogram (ECG) are ST-segment depression and T wave inversion; they are more likely to be present while the patient is symptomatic. Comparison with a recent ECG is important because dynamic ST-segment depressions as little as 0.05 mV are a sensitive (albeit not very specific) marker for NSTEMI-ACS. Greater degrees of ST-segment depression predict poorer outcomes, however, even when adjusted for other prognostic factors.^{9,10} Transient ST-segment elevation lasting less than 20 minutes occurs in up to 10% of patients and suggests either coronary vasospasm or an aborted infarction. Deep (>0.2 mV) T wave inversions are compatible with, but not necessarily diagnostic of NSTEMI-ACS, whereas isolated T wave inversions of lesser magnitude are not particularly helpful given their low specificity. In patients with definite NSTEMI-ACS, findings on the ECG may be normal or nondiagnostic in more than half of patients. Because ischemia may occur in a territory that is not well represented on the standard 12-lead ECG (see below) or because the patient may have episodic ischemia that is missed on the initial ECG, tracings should be repeated every 20 to 30 minutes until the symptoms resolve, the diagnosis of MI is established or excluded, or an alternative diagnosis is made.

Coronary angiography identifies a culprit lesion in the circumflex coronary artery in a third of patients with high-risk NSTEMI-ACS.¹¹ Because the standard 12-lead ECG does not represent this territory well, assessment of posterior leads V₇ through V₉ should be considered in patients with a history suggestive of ACS and a nondiagnostic initial ECG. Similarly, ACS caused by isolated involvement of an acute marginal branch of the right coronary artery is often not apparent on the standard 12-lead ECG but may be suspected from leads V₃R and V₄R.¹² Therefore it is useful to obtain these extra leads in patients suspected of having ACS but with normal findings on a 12-lead ECG.

Continuous monitoring of the ECG in the days following NSTEMI-ACS can identify patients at higher risk for recurrent events. ST-segment depressions noted on such monitoring within the first week after NSTEMI-ACS are associated with an increased risk for reinfarction and death.¹³

Laboratory

Biomarkers reflecting the pathogenesis of NSTEMI-ACS aid in diagnosis and prognosis. They include markers of myocyte necrosis, hemodynamic perturbation, vascular damage, accelerated atherosclerosis, and inflammation (Fig. 53-4). During the past decade, cardiac-specific troponins (cTnI and cTnT) have become the biomarkers of choice to identify myocardial necrosis and hence distinguish NSTEMI from UA. Several pathobiologic mechanisms can lead to the release of detectable levels of cTn in blood (Table 53-1). Because of differences among assays, there is consensus that the diagnosis of acute MI requires an elevation in cTnI or cTnT above the 99th percentile of the normal range for the specific assay used,¹⁴ a typical temporal rise and decline when serial samples are tested, and a clinical picture consistent with ACS.

Although elevated cTn usually reflects myocardial necrosis, it does not always reflect MI. Abnormal elevations have been observed with a number of conditions, including heart failure, pulmonary embolism, myocarditis, pericarditis, transplant rejection, chemotherapy, and direct or indirect cardiac trauma. Furthermore, cTnI may be elevated chronically at a low-grade level in patients with severe CKD (stages IV and V), and all cTn is cleared more slowly in patients with impaired renal function. Therefore interpretation of the clinical significance of elevated cTn in such patients requires care. In fact, an estimated 60% to 70% of individuals with chest discomfort seen in an emergency department will have measurable cTn concentrations,¹⁵ but only a minority of them are experiencing acute MI.

Patients with clinical findings suggestive of NSTEMI-ACS should have serial measurements of cTn beginning at initial evaluation. Newer high-sensitivity assays available in Europe (but not in the United States as of 2012) can exclude myocardial necrosis if two values measured 3 hours apart are both normal.¹⁶ However, the specificity of high-sensitivity cTn assays in the diagnosis of NSTEMI-ACS may be as

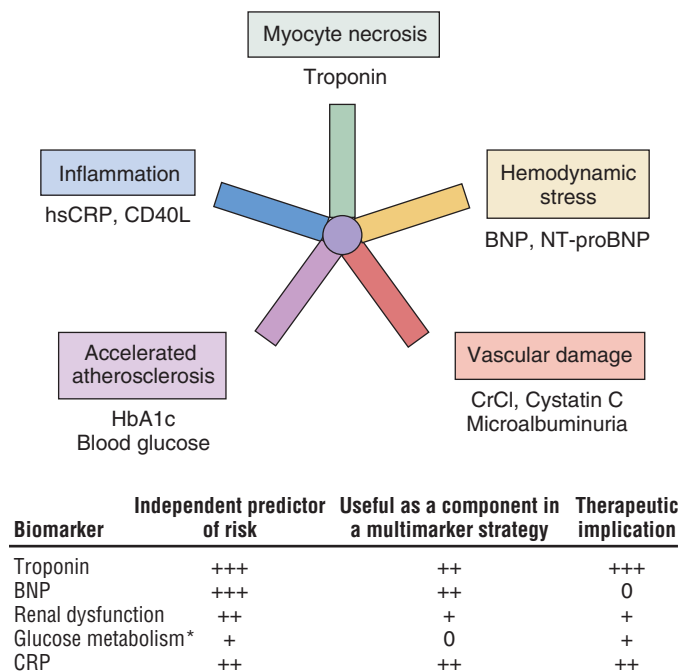

FIGURE 53-4 Multimarker approach for risk stratification in ACSs. *Glucose metabolism = hyperglycemia or elevated HbA1C. BNP = brain natriuretic peptide; CD40L = CD40 ligand; CrCl = creatinine clearance; CRP = C-reactive protein; HbA1c = glycated hemoglobin; hsCRP = high-sensitivity C-reactive protein; NT-proBNP = N-terminal brain natriuretic peptide. (Modified from Morrow DA, Braunwald E: *Future of biomarkers in acute coronary syndromes: Moving toward a multimarker strategy*. *Circulation* 108:250, 2003.)

TABLE 53-1 Mechanisms of Troponin Release

TYPE	EXAMPLES/EXPLANATION
Myocyte* necrosis	Ischemia, infarction, inflammation, infiltration, trauma, toxic/metabolic (e.g., sepsis)
Apoptosis	Programmed cell death because of activation of caspases
Normal myocyte turnover	Natural low-grade annual turnover of myocytes (unclear whether this can be detected in the systemic circulation with current assays)
Cellular release of proteolytic troponin degradation products	Creation of small fragments that pass through the intact myocyte membrane without cell death
Increased cellular wall permeability	Reversible injury to myocyte membranes resulting in altered permeability (e.g., secondary to stretch, ischemia)
Formation and release of membranous blebs	Active secretion of vesicles or membrane expression with shedding (e.g., secondary to hypoxia)

*Diseased skeletal muscle may also cause increases in circulating cTnT (but not in cTnI).
 From White HD: *Pathobiology of troponin elevations: Do elevations occur with myocardial ischemia as well as necrosis?* *J Am Coll Cardiol* 57:2406, 2011.

low as 60%, even in patients with established CHD.¹⁷ The fourth-generation cTn assays currently used in the United States are less sensitive than the so-called high-sensitivity assays, and two negative cTn assays at least 6 to 9 hours apart are needed to exclude MI. The change in cTn between measurements appears to be more important than the actual concentration and can help distinguish MI from other processes that cause elevated cTn.¹⁸ In addition, normal early cTn levels are useful in the identification of patients at very low risk for cardiovascular events over the next 6 months¹⁹; they are useful in long-term prognostication as well (Fig. 53-5).

FIGURE 53-5 Survival of patients with MI according to baseline troponin. **A**, Mortality. **B**, MI and congestive heart failure. Individuals with a possible MI and low levels of cTnI (0.02 to 0.04 ng/mL), which are below the 99th percentile for this assay, had more subsequent events than did those with undetectable values. (From Kavsak PA, Newman AM, Lustig V, et al: *Long-term health outcomes associated with detectable troponin I concentrations*. *Clin Chem* 53:220, 2007.)

As already noted, an important consequence of the use of increasingly sensitive cTn assays is that the fraction of NSTEMI-ACS patients with UA has decreased in favor of NSTEMI. This reclassification is important because even minor elevations in cTn are associated with poorer outcomes than in patients without evidence of myonecrosis. Reclassification from UA to NSTEMI can lead to more aggressive treatment of patients with a low-level, “positive” cTn assay.²⁰

Other biomarkers also increase in the days to weeks following NSTEMI-ACS. Natriuretic peptides (i.e., brain natriuretic peptide [BNP] and N-terminal pro-BNP) rise in proportion to the degree of ventricular distention and correlate with the risk for adverse events.^{21,22} In patients with NSTEMI-ACS, a baseline BNP measured on average 40 hours after the onset of symptoms correlated strongly with risk for death, heart failure, and MI through 10 months in a graded fashion.²¹ Baseline natriuretic peptide levels also help identify patients more likely to benefit from more aggressive treatments, including intensive anti-ischemic regimens,²² aggressive statin therapy,²³ and early coronary revascularization.²⁴

C-reactive protein (CRP) is a marker of inflammation that is elevated following ACS, and persistently elevated levels after discharge are associated with increased long-term cardiovascular risk. Elevated levels of fasting blood glucose and glycosylated hemoglobin indicate the presence of diabetes mellitus or metabolic syndrome and portend accelerated atherosclerosis and an increased risk for cardiovascular events in both the short and long term.²⁵ Renal dysfunction, as reflected by elevated levels of cystatin C and creatinine, is associated with an increase in cardiovascular events, including cardiovascular mortality, in patients with NSTEMI-ACS.

Several novel biomarkers can help improve prognostication in patients with NSTEMI-ACS (Table 53-2). These biomarkers tend to fall

TABLE 53-2 Emerging Biomarkers in Acute Coronary Syndromes

MARKER NAME	DESCRIPTION	REFERENCE
Markers That Predict Death and/or Ischemic Events		
Growth differentiation factor-15	Member of the transforming growth factor-beta cytokine superfamily that is released from cardiomyocytes after ischemia and reperfusion injury	26
Heart-type fatty acid-binding protein	Cytoplasmic protein involved in intracellular uptake and buffering of free fatty acids in the myocardium	27
Myeloperoxidase	A hemeprotein released during degranulation of neutrophils and some monocytes	28
Pregnancy-associated plasma protein A	Zinc-dependent matrix metalloproteinase abundantly expressed in eroded and ruptured plaque but only minimally expressed in stable plaque	29
Placental growth factor	Member of the vascular endothelial growth factor family that is strongly upregulated in atherosclerotic lesions and acts as a primary inflammatory instigator of atherosclerotic plaque instability	30
Secretory phospholipase A ₂	Hydrolyzes phospholipids to generate lysophospholipids and fatty acids, thereby enhancing susceptibility of the vessel to atherogenesis	31
Interleukin-6	Stimulator of hepatic synthesis of C-reactive protein	32
Chemokine ligand-5 and ligand-18	Mediators of monocyte recruitment induced by ischemia	33
Markers That Predict Heart Failure		
Midregional proadrenomedullin	Peptide fragment of the vasodilatory peptide adrenomedullin	34
Neopterin	Marker of monocyte activation	35
Osteoprotegerin	Modulator of immune function and inflammation	36

into two general categories: (1) markers that predict death and/or ischemic events²⁶⁻³³ and (2) markers that predict heart failure.³⁴⁻³⁶

Multimarker approaches involving biomarkers that are independent predictors of outcome are increasingly being used.³⁷ One such approach uses three common biomarkers (cTn, CRP, and BNP), with an increasing number of abnormal markers correlating with a stepwise higher risk for subsequent ischemic complications.³⁸

Measurement of serum lipids, including low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol and triglyceride, is useful in identifying important, treatable risk factors for coronary atherothrombosis (see Chapter 45). The first available sample should be used to guide therapy. Evaluation for other secondary causes of NSTEMI-ACS³⁹ may also be appropriate in selected patients (e.g., determining the presence of hypoxemia, anemia, and disturbed thyroid function) because such “secondary” NSTEMI-ACS can often be treated and recurrences prevented.

Noninvasive Testing

Goals of noninvasive testing in patients with suspected NSTEMI-ACS include (1) determining the presence or absence of coronary artery disease (CAD); (2) establishing CAD as the cause of the elevated cTn in patients with other possible explanations; (3) evaluating the extent of residual ischemia after medical therapy has been initiated, thus guiding further therapy; (4) localizing the ischemia before a planned percutaneous coronary intervention (PCI) in patients with multivessel disease; and (5) assessment of left ventricular function.

The safety of early stress testing in patients with NSTEMI-ACS has been debated, but pharmacologic or symptom-limited stress testing appears to be safe after a period of at least 24 hours of stabilization without symptoms of active ischemia⁴⁰; contraindications include active ischemia or other signs of hemodynamic or electrical instability.

The merits of various modalities of stress testing have been compared (see Chapter 13). Exercise stress myocardial perfusion imaging with sestamibi (Chapter 16) and stress echocardiography with dobutamine have slightly more sensitivity than electrocardiographic exercise stress testing does alone. A useful approach is to individualize the choice based on patient characteristics, local availability, and expertise in interpretation. For most patients, electrocardiographic exercise stress testing is recommended if the ECG at rest lacks ST-segment abnormalities. If ST abnormalities exist at rest or if

the patient is unable to exercise or cannot achieve a significant workload during exercise, pharmacologic stress perfusion or echocardiographic imaging is recommended. Findings consistent with high risk (e.g., severe ischemia as reflected by ST-segment depression ≥ 0.2 mV, hypotension, ventricular tachyarrhythmia, new or worsening left ventricular dysfunction) are indications to proceed rapidly with coronary angiography with the intent of performing revascularization if the coronary anatomy is appropriate.

Echocardiography is useful in the assessment of left ventricular systolic and diastolic function and can also be used to identify left atrial dilation,⁴¹ functional mitral regurgitation,⁴² tricuspid annular plane systolic excursion,⁴³ diastolic dysfunction,⁴⁴ ventricular mechanical dyssynchrony,⁴⁵ and ultrasound lung comets⁴³ (extravascular lung fluid observed on thoracic ultrasound scanning)—each of which has been associated with an adverse prognosis in patients with NSTEMI-ACS.

Contrast-enhanced coronary CTA (CCTA) in patients with or suspected of having NSTEMI-ACS can help establish the diagnosis of epicardial CAD in patients with equivocal signs and symptoms and identify unstable plaque at high risk for rupture. Detailed analysis of plaque morphology has identified two characteristics—positive vessel remodeling and low-attenuation plaque of lipid-rich lesions (Fig. 53-6)—that were associated with plaque rupture and ACS in 1059 patients observed for clinical events for an average of 27 months after imaging.⁴⁶

CCTA can be used to exclude ACS rapidly in hospital emergency departments in patients with suspected ACS. Three randomized trials⁴⁷⁻⁴⁹ (see Chapter 18) examined the value of early CCTA in assessment of patients in the emergency department. Whether a CCTA approach to patients suspected of having ACS will be superior to judicious outpatient clinical follow-up of low-risk patients with normal cTn levels remains to be determined.

Cardiac magnetic resonance (CMR) using a rapid-scan protocol can provide precise measurements of ventricular function and volumes, evaluate ventricular wall edema, identify areas of infarction versus hibernating myocardium, establish the presence of myocardial perfusion, quantify wall motion and the ejection fraction, and identify myocardium at risk in patients with NSTEMI-ACS.⁵⁰ These detailed assessments can then help guide PCI, particularly when the culprit lesion is uncertain—such as in patients with multivessel disease or with borderline stenoses.

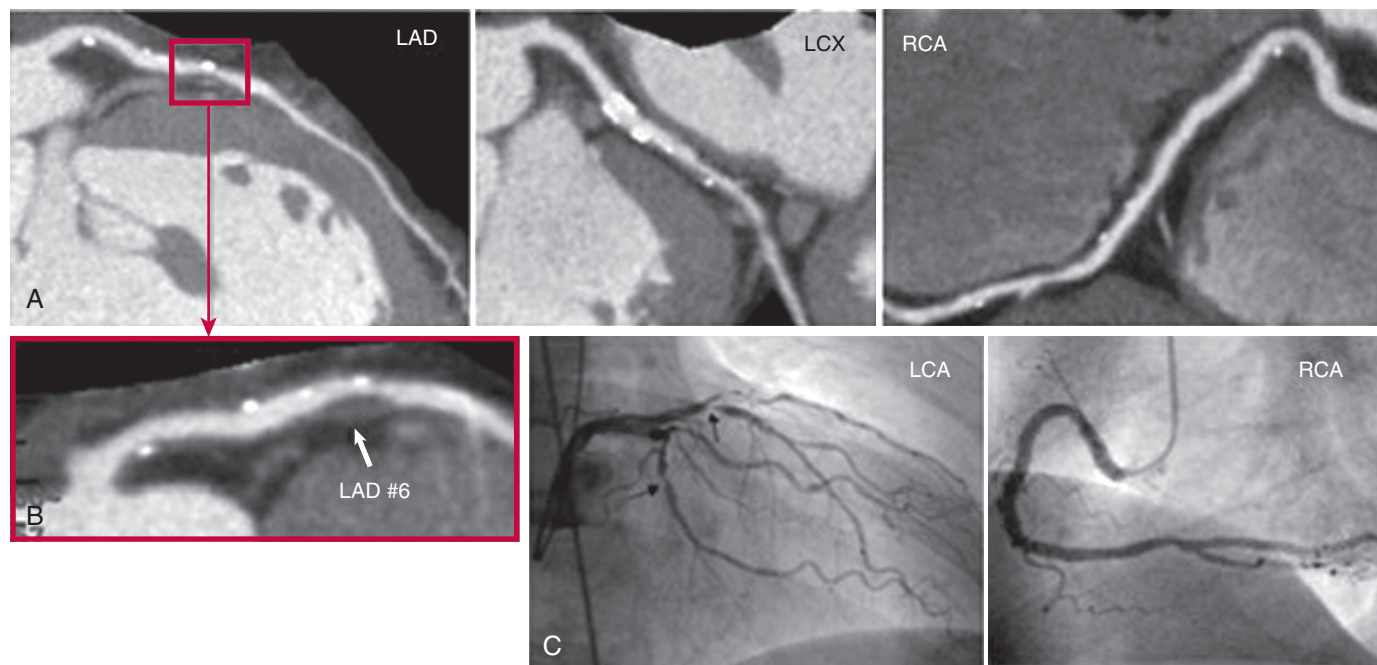

FIGURE 53-6 Angiographic characteristics of high-risk plaque. **A**, Curved multiplanar reformatted images of the left anterior descending artery (LAD), left circumflex artery (LCX), and right coronary artery (RCA). **B**, Positive remodeling, low-attenuation plaque, and spotty calcification were detected in the LAD on CTA. **C**, An ACS involving the high-risk plaque seen earlier in the LAD (arrow) occurred 6 months after CTA. (From Motoyama S, Sarai M, Harigaya H, et al: *Computed tomographic angiography characteristics of atherosclerotic plaques subsequently resulting in acute coronary syndrome*. *J Am Coll Cardiol* 54:49, 2009.)

Invasive Imaging

Invasive coronary angiography has been the reference technique for imaging the coronary arterial tree for more than five decades. The culprit lesion in NSTEMI-ACS typically exhibits an eccentric stenosis with scalloped or overhanging edges and a narrow neck (see Chapter 20). These angiographic findings may represent disrupted atherosclerotic plaque and/or thrombus. Features suggesting thrombus include globular intraluminal masses with a rounded or polypoid shape. “Haziness” of a lesion suggests the presence of thrombus, but this finding is not specific.

Approximately 85% of patients with a clinical diagnosis of NSTEMI-ACS have significant coronary obstruction (i.e., >50% stenosis of the luminal diameter) in at least one major coronary artery. Most have obstructive disease involving multiple epicardial arteries (≈10% with left main coronary artery, ≈35% with three-vessel disease, ≈20% with two-vessel disease), whereas only approximately 20% have isolated single-vessel disease.⁵¹ The remaining 15% have no evidence of significant coronary obstruction on angiography; this finding occurs more frequently in women and nonwhite individuals. In such patients, NSTEMI-ACS, if present, may be related to microvascular coronary obstruction, endothelial dysfunction, or coronary artery spasm and is generally associated with a more favorable prognosis. The absence of coronary obstruction on angiography, however, should prompt a search for causes of the symptoms other than coronary atherosclerosis.

Two invasive cross-sectional imaging techniques—IVUS and OCT—can provide additional detail regarding plaque morphology and are sometimes used clinically to visualize the deployment of intracoronary stents. A large necrotic core visualized by IVUS in culprit lesions undergoing intracoronary stenting can predict the no-reflow phenomenon after stenting.⁵² OCT of plaque in patients with ACS has demonstrated its lipid content, calcification, and thrombus.⁵³ Plaque with a thin fibrous cap is associated with a high risk for rupture if the hemoglobin A1c content is 8.0% or higher.⁵³

Even though several other invasive techniques—including angioscopy, intravascular magnetic resonance imaging (MRI), near-infrared spectroscopy, palpography, thermoscopy, and shear stress imaging—have been developed, large-scale prospective evaluation of these diagnostic techniques is needed to assess and compare their clinical usefulness and cost-effectiveness.

Risk Assessment

Residual Risk

The risk for recurrent ischemic events following an episode of ACS depends as much on the presence and stability of multifocal lesions as on the culprit lesion responsible for the initial event.⁵⁴ Thus because aggressive interventional approaches are increasingly being successful in the treatment of culprit lesions, aggressive medical management of the remaining plaque is required to prevent recurrent events.⁵⁴ The percentage of patients with more than one active plaque on angiography has been correlated with the level of high-sensitivity CRP (hsCRP).⁵⁵ These findings provide an important pathophysiologic link between inflammation, more diffuse active CAD, and recurrent cardiac events in the months to years following a clinical ACS event.

Natural History

Patients with UA, defined as NSTEMI-ACS without abnormal elevation of cTn, have lower short-term mortality (<2.0% at 30 days) than do those with NSTEMI or STEMI.⁵⁶ The early mortality risk with NSTEMI is related to the extent of myocardial damage and resulting hemodynamic compromise and is lower than in patients with STEMI, who usually have larger infarcts.^{4,56} In contrast, long-term outcomes with respect to both mortality and nonfatal events are worse in patients with NSTEMI-ACS than in those with STEMI.⁵⁷ This finding probably results from the greater age, extent of CAD, previous MI, comorbid conditions (such as diabetes and impaired renal function), and likelihood of recurrence of ACS in patients with NSTEMI-ACS than in those with STEMI.

Combined Risk Assessment Scores

Several risk scores that integrate clinical variables and findings on the ECG and/or from serum cardiac markers have been developed for patients with NSTEMI-ACS.⁵⁸⁻⁶⁰ The TIMI (Thrombolysis In Myocardial Ischemia) risk score (Fig. 53-7) identifies seven independent risk factors; their sum correlates directly with death or recurrent ischemic events.⁵⁸ This simple, rapid assessment of risk at initial evaluation identifies high-risk patients who can derive benefit from an early invasive strategy and more intensive antithrombotic therapy. This risk score also predicts the severity of angiographic findings, including

FIGURE 53-7 TIMI risk score for NSTEMI-ACS. The number of risk factors present is counted. (From Antman EM, Cohen M, Bernink PJ, et al: *The TIMI risk score for unstable anginal/non-ST elevation MI: A method for prognostication and therapeutic decision making*. JAMA 284:835, 2000.)

the extent of CAD,⁶¹ thrombus burden, and flow impairment.⁶² An even simpler score, the TIMI risk index (age in decades \times heart rate/systolic blood pressure), predicts mortality in patients with NSTEMI.⁶³

The GRACE (Global Registry of Acute Coronary Events) risk score⁶⁰ has also identified risk factors that are independently associated with increased mortality. Although perhaps more accurate, it is more complex than the TIMI risk score and is not easily calculated by hand.

MANAGEMENT

Treatment of NSTEMI-ACS consists of two phases: acute management directed at the clinical symptoms and stabilization of the culprit lesion or lesions and longer-term therapy aimed at preventing progression of the underlying disease and future plaque rupture/erosion. In a prospective natural history study of patients with NSTEMI-ACS who successfully underwent PCI of the culprit lesion, 20% had a second ACS event over a mean of 3.4 years, with half of these events being ascribed to the original culprit lesion and the other half to a new lesion.⁵⁴

General

Patients with new or worsening chest discomfort or an anginal equivalent symptom suggestive of ACS should be transported rapidly to the emergency department of a hospital by an ambulance, if possible, and evaluated immediately (Fig. 53-8).⁶⁴ The initial evaluation should include a directed history and physical examination and an ECG performed within 10 minutes of arrival.⁶⁵ Blood specimens for cTn assay should be obtained with expedited assessment via either a point-of-care device or laboratory measurement that can provide results within 60 minutes. Additional laboratory studies, such as a complete blood count, serum electrolytes, creatinine, and glucose, can help guide early management treatments and strategy.

Patients with elevated cTn or new ST-segment abnormalities or deemed to be at moderate or high risk based on a validated risk score should be admitted to a specialized cardiovascular or intensive care unit. Patients with UA but without elevated cTn and ischemic electrocardiographic changes should generally be admitted to a monitored bed, preferably in a cardiovascular step-down unit.⁶ In these settings,

continuous electrocardiographic monitoring with telemetry detects tachyarrhythmias, alterations in atrioventricular and intraventricular conduction, and changes in ST-segment deviation. Patients should be placed at bed rest, arterial O₂ saturation should be assessed continuously by oximetry, and supplemental O₂ is advisable in patients with reduced arterial O₂ saturation (<90%) and/or in those with heart failure and pulmonary rales. Ambulation, as tolerated, is permitted if the patient has been stable without recurrent chest discomfort or changes on the ECG for at least 12 to 24 hours. Patients with atypical symptoms and low risk or those who have symptoms more consistent with another noncardiac cause may be observed in the emergency department or a short-stay unit. A second cTn assay should be performed 3 to 6 hours after the first, and/or further assessment with noninvasive imaging or stress testing may be considered to permit rapid exclusion of ACS.

Anti-Ischemic Therapy

A primary goal in the management of NSTEMI-ACS is relief of ischemic symptoms and prevention of the severe short- and long-term sequelae, including recurrent MI, heart failure, and death.

Nitrates

Nitrates are endothelium-independent vasodilators that both increase myocardial blood flow by coronary vasodilation and reduce myocardial oxygen demand by lowering cardiac preload through venodilation and reduce cardiac afterload by inducing arterial dilation and thereby diminishing ventricular wall stress.

Sublingual (or buccal) nitroglycerin (0.3 to 0.6 mg up to three times at 5-minute intervals) should be administered to patients without hypotension, beginning even before hospital arrival whenever possible. If ischemic symptoms persist and/or the patient is hypertensive or in heart failure, intravenous nitroglycerin (5 to 10 μ g/min, with the dose increased gradually to 200 μ g/min as needed) should be initiated as long as systolic blood pressure remains higher than 100 mm Hg. Topical or long-acting oral nitrates can be used if the patient has been free of pain for 12 to 24 hours. Tolerance to the anti-ischemic effects of nitrates may develop within 12 to 24 hours and can be ameliorated by nitrate-free intervals. If symptoms do not allow nitrate-free intervals, increasing the dose may be effective. Discontinuation of high doses of nitrates, particularly when administered intravenously, should be performed in a gradual manner to prevent recurrent ischemia.

Contraindications to nitrate use are hypotension or the use of phosphodiesterase type 5 (PDE-5) inhibitors (e.g., sildenafil, tadalafil, vardenafil) within the previous 24 to 48 hours. PDE-5 inhibitors reduce the breakdown of cyclic guanosine monophosphate (cGMP) and thereby cause an exaggeration and prolongation of the vasodilator effects of nitrates, which can result in severe hypotension, myocardial ischemia, or even death. Nitrates should be used with caution in patients with severe aortic valve stenosis, hypertrophic cardiomyopathy with left ventricular outflow obstruction at rest, right ventricular infarction, or hemodynamically significant pulmonary embolism.

Beta-Adrenergic Receptor Blocking Agents

Much of the evidence supporting the use of beta-adrenergic receptor blockers (beta blockers) for NSTEMI-ACS has been extrapolated from clinical trials, predominantly in patients with STEMI, in which it was demonstrated that beta blockers reduce reinfarction, ventricular fibrillation, and death (see Chapter 52). A systematic review pooling data on patients with UA from trials performed more than 25 years ago (in the pre-cTn era) suggested that beta blockers reduce the risk for progression to MI.⁶⁶ Whether beta blockers have similar efficacy in the modern era of intensive pharmacologic management and early revascularization is not clear.

Oral beta-blocking agents in doses used for chronic stable angina (see Chapter 54) should be initiated within the first 24 hours,^{6,66} with the following exceptions: (1) signs of decompensated heart failure; (2) evidence of a low-cardiac output state; (3) increased

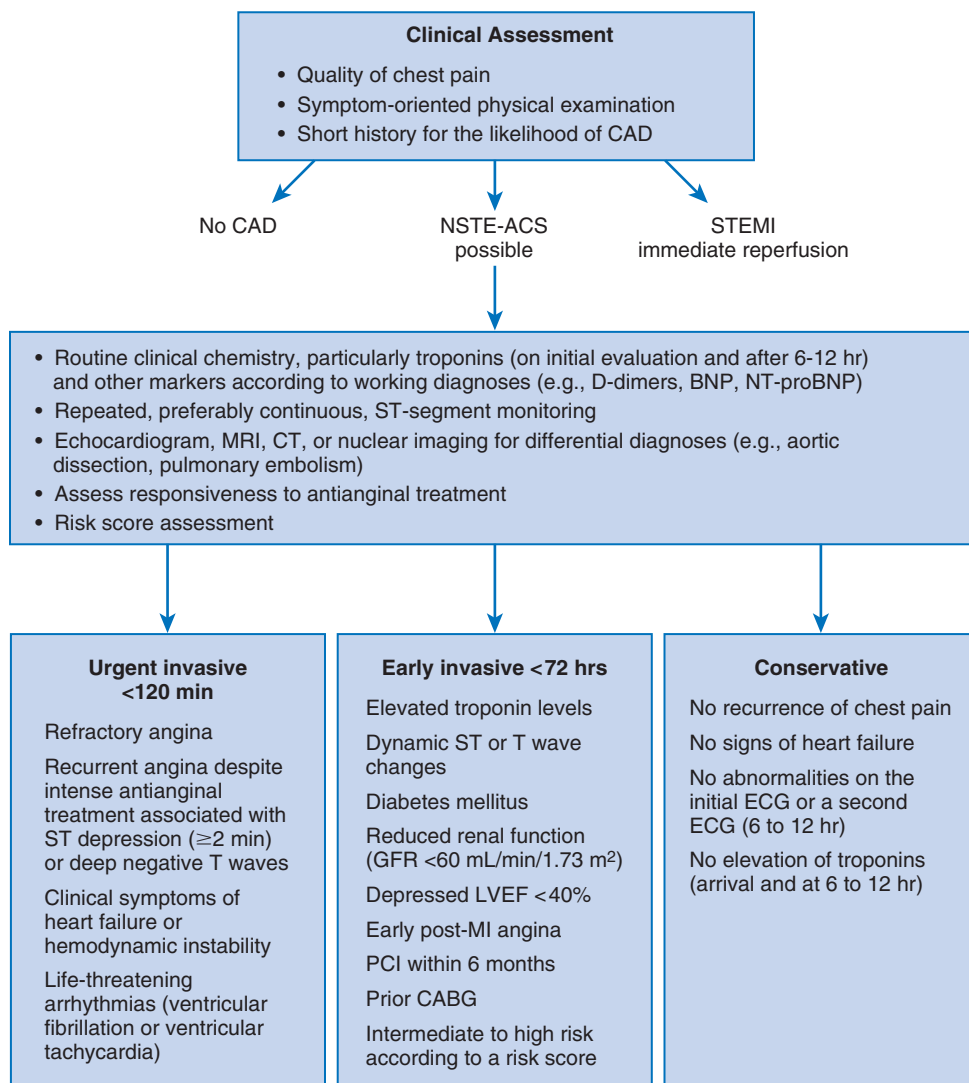

FIGURE 53-8 Decision-making algorithm for the management of NSTEMI-ACS. CABG = coronary artery bypass grafting; GFR = glomerular filtration rate; LVEF = left ventricular ejection fraction. (From Bassand JP, Hamm CW: *Diagnosis and treatment of non-ST-segment elevation acute coronary syndromes: European Society of Cardiology guidelines. Eur Heart J* 32:369, 2011.)

risk for cardiogenic shock; or (4) atrioventricular block, asthma, or reactive airway disease. Beta blockers can be administered to patients with heart failure once their condition has stabilized. If ischemia and/or chest pain persists despite intravenous nitrate therapy, intravenous beta blockers may be used cautiously, followed by oral administration. Intravenous beta blockers should be avoided in patients with acute MI and heart failure at initial evaluation.⁶⁷ The choice of beta blockers can be individualized by taking into account the drug's pharmacokinetics, physician familiarity, and cost, but beta blockers with intrinsic sympathomimetic activity, such as pindolol, should generally be avoided.

Morphine

In patients with persistent pain despite therapy with nitrates and beta blockers (see below), intravenous boluses of morphine sulfate at doses of 2 to 5 mg may be administered every 10 minutes for up to three times while carefully monitoring blood pressure, respiration, and mental status.⁶ Morphine may act as both an analgesic and an anxiolytic, and its venodilator effects may be beneficial by reducing ventricular preload. The latter action is especially useful in patients with pulmonary congestion. However, morphine may also cause hypotension, and if it occurs, supine positioning and intravenous saline should be used to restore blood pressure; pressors are rarely needed. If respiratory depression develops, naloxone

(0.4 to 2.0 mg) may be given. Contraindications include hypotension and allergy to morphine, for which meperidine can be substituted.

Calcium Channel Blockers

These agents have vasodilator effects and reduce arterial pressure. Some, such as verapamil and diltiazem, also slow the heart rate, reduce myocardial contractility, and thereby reduce O₂ requirements. Early studies suggested that diltiazem may reduce the incidence of recurrent MI.⁶⁸ Calcium channel blockers have been effective in reducing ischemia in patients with NSTEMI-ACS and persistent ischemia despite treatment with full-dose nitrates and beta blockers, as well as in patients with contraindications to beta blockers (see above) and in those with hypertension.^{65,69} Such patients should receive nondihydropyridine calcium channel-blocking agents that lower the heart rate. The short-acting formulation of the dihydropyridine nifedipine, which accelerates the heart rate, can cause harm in patients with ACS when not coadministered with a beta blocker. No harm has been observed with long-term treatment with the long-acting dihydropyridines—amlodipine or felodipine—in patients with documented left ventricular dysfunction and CAD,⁷⁰ thus indicating that these agents may be safe in patients with NSTEMI-ACS and left ventricular dysfunction.⁷¹

Ranolazine

This novel antianginal agent exerts its effects without altering the heart rate or blood pressure. Its predominant mechanism of action is inhibition of the late sodium current in myocardial cells, thereby reducing some of the deleterious effects attributed to the

overload of intracellular sodium and calcium during ischemia (see Chapter 21). Ranolazine reduces ischemic episodes and the need for nitroglycerin in patients with chronic stable angina, both as monotherapy and in combination with calcium channel blockers or beta blockers. Ranolazine underwent evaluation in a placebo-controlled trial of 6560 patients with NSTEMI-ACS who were monitored for an average of almost 1 year.⁷² In the overall trial population, ranolazine did not reduce the primary composite outcome of cardiovascular death, MI, or recurrent ischemia but did decrease the incidence of recurrent ischemia. The primary outcome, however, was reduced significantly in the subgroups of patients with elevated natriuretic peptides (by 21%) and in those with previous stable angina (by 14%).⁷³

Antiplatelet Therapy

Given the central role of platelet activation and aggregation in the pathogenesis of ACS, it comes as no surprise that antiplatelet therapy represents a key component of treatment in patients with NSTEMI-ACS (Table 53-3; also see Fig. 53-3).

Aspirin (Acetylsalicylic Acid)

Acetylsalicylic acid (ASA) acetylates platelet cyclooxygenase-1 (COX-1), which blocks the synthesis and release of TxA₂, a platelet activator,

TABLE 53-3 Recommendations for Oral Antiplatelet Agents⁶⁵

RECOMMENDATIONS	CLASS	LEVEL
Aspirin should be given to all patients without contraindications at an initial loading dose of 150-300 mg and at a maintenance dose of 75-100 mg daily long-term regardless of treatment strategy	I	A
A P2Y ₁₂ inhibitor should be added to aspirin as soon as possible and maintained over a period of 12 months unless there are contraindications such as excessive risk for bleeding	I	A
A proton pump inhibitor (preferably not omeprazole) in combination with DAPT is recommended in patients with a history of gastrointestinal hemorrhage or peptic ulcer and is appropriate for patients with multiple other risk factors (<i>Helicobacter pylori</i> infection, ≥65 years, concurrent use of anticoagulants or steroids)	I	A
Prolonged or permanent withdrawal of P2Y ₁₂ inhibitors within 12 months after the index event is discouraged unless clinically indicated	I	C
Ticagrelor (180-mg loading dose, 90 mg twice daily) is recommended for all patients at moderate to high risk for ischemic events (e.g., elevated troponins), regardless of initial treatment strategy and including those pretreated with clopidogrel (which should be discontinued when ticagrelor is commenced)	I	B
Prasugrel (60-mg loading dose, 10-mg daily dose) is recommended for P2Y ₁₂ inhibitor-naïve patients (especially diabetic individuals) in whom the coronary anatomy is known and who are proceeding to PCI unless there is a high risk for life-threatening bleeding or other contraindications [†]	I	B
Clopidogrel (300-mg loading dose, 75-mg daily dose) is recommended for patients who cannot receive ticagrelor or prasugrel	I	A
A 600-mg loading dose of clopidogrel (or a supplementary 300-mg dose at PCI following an initial 300-mg loading dose) is recommended for patients scheduled for an invasive strategy when ticagrelor or prasugrel is not an option	I	B
A higher maintenance dose of clopidogrel, 150 mg daily, should be considered for the first 7 days in patients managed with PCI and without increased risk for bleeding	IIa	B
Increasing the maintenance dose of clopidogrel based on platelet function testing is not advised as routine but may be considered in selected cases	IIb	B
Genotyping and/or platelet function testing may be considered in selected cases when clopidogrel is used	IIb	B
In patients pretreated with P2Y ₁₂ inhibitors who need to undergo nonemergency major surgery (including CABG), postponing surgery for at least for 5 days after cessation of ticagrelor or clopidogrel and for 7 days for prasugrel should be considered if clinically feasible and if the patient is not at high risk for ischemic events	IIa	C
Starting (or restarting) ticagrelor or clopidogrel after CABG should be considered as soon as considered safe	IIa	B
The combination of aspirin with an NSAID (selective COX-2 inhibitors and nonselective NSAID) is not recommended	III	C

*Class of recommendation.

[†]Level of evidence.

[‡]Prasugrel is given a IIa recommendation as the overall indication, including clopidogrel-pretreated patients and/or unknown coronary anatomy. The class I recommendation here refers to the specifically defined subgroup.

CABG = coronary artery bypass grafting; DAPT = dual antiplatelet therapy; NSAID = nonsteroidal anti-inflammatory drug.

From Hamm CW, Bassand JP, Agewall S, et al: ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation: The Task Force for the Management of Acute Coronary Syndromes (ACS) in Patients Presenting Without Persistent ST-Segment Elevation of the European Society of Cardiology (ESC). *Eur Heart J* 32:2999, 2011.

thereby decreasing platelet aggregation and arterial thrombus formation. Because the inhibition of COX-1 by aspirin is irreversible, the antiplatelet effects last for the lifetime of the platelets—approximately 7 to 10 days. Several placebo-controlled trials have demonstrated the benefit of aspirin in patients with NSTEMI-ACS.⁷⁴ In addition to reducing adverse clinical events early in the course of treatment, aspirin also reduces the frequency of ischemic events in secondary prevention. It is a cornerstone of antiplatelet therapy in patients with all forms of ACS.⁷⁵

Even though doses of ASA in randomized trials have ranged from 50 to 1300 mg/day, there does not appear to be a dose-response effect on efficacy, but gastrointestinal bleeding is increased at higher doses.⁷⁴ The CURRENT OASIS-7 (Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events—Seventh Organization to Assess Strategies in Ischemic Symptoms)⁷⁶ trial randomly assigned 25,086 patients with ACS to receive high-dose (300 to 325 mg/day) or low-dose (75 to 100 mg/day) ASA for 30 days (and to high-dose versus regular-dose clopidogrel; see below). No difference in the risk for cardiovascular death, MI, or stroke was observed between the two doses, but gastrointestinal bleeding increased with the higher dose. Guidelines recommend that in patients with NSTEMI-ACS in whom continual ASA therapy has not been prescribed, the initial loading dose should be 162 to 325 mg, followed by a maintenance dose of 75 to 100 mg daily.⁶ Data from PLATO (Study of Platelet Inhibition and Patient Outcomes), a large trial of ticagrelor (see Chapter 82), an

oral antiplatelet agent that inhibits the P2Y₁₂ receptor, provides another reason to favor low-dose ASA.⁷⁷

So-called ASA resistance may occur during chronic therapy,⁷⁸ with 2% to 8% of patients exhibiting a limited antiplatelet effect (i.e., minimal change in inhibition of platelet aggregation). These patients tend to have a greater risk for recurrent cardiac events.⁷⁹ Causes of ASA resistance are varied and include poor compliance (pseudoresistance), reduced absorption, interaction with ibuprofen, overexpression of COX-2 mRNA, and use of enteric-coated dosage forms. Rarely, a genetic or other intrinsic reason for minimal response to ASA is present. There is no evidence, however, that routine monitoring of antiplatelet effects with adjustment of the dose is a clinically effective strategy.

Contraindications to ASA include documented allergy (e.g., ASA-induced asthma), nasal polyps, active bleeding, or a known platelet disorder. Dyspepsia or other gastrointestinal symptoms with long-term ASA therapy (i.e., ASA intolerance) does not usually preclude therapy in the short term. In patients who have an allergy or who cannot tolerate ASA, desensitization or substituting clopidogrel, prasugrel, or ticagrelor is recommended.⁷⁵

P2Y₁₂ (Adenosine Diphosphate) Inhibitors

Management of ACS now routinely includes dual antiplatelet therapy (DAPT), which consists of ASA and a P2Y₁₂ inhibitor (see Fig. 53-3). The latter falls into two groups: thienopyridines (ticlopidine,

clopidogrel, and prasugrel) and a cyclopentyl-triazolopyrimidine (ticagrelor). Thienopyridines act by irreversibly blocking binding of ADP to the platelet surface P2Y₁₂ receptor, thereby interfering with both platelet activation and aggregation by ADP. They are prodrugs that require oxidation by the hepatic cytochrome P-450 (CYP) system to form active metabolites.⁸⁰ Thienopyridines also reduce fibrinogen, blood viscosity, and erythrocyte deformability and aggregability through mechanisms that appear to be independent of ADP. In contrast, ticagrelor acts directly as a reversible blocker of the P2Y₁₂ receptor. Drugs that inhibit the CYP system do not affect ticagrelor.

Clopidogrel

This drug largely avoids the hematologic complications (neutropenia and, rarely, thrombotic thrombocytopenic purpura) associated with ticlopidine, the first widely used thienopyridine. When clopidogrel is absorbed, approximately 85% is hydrolyzed by circulating esterase and thus rendered inactive. The remaining clopidogrel must be oxidized by the hepatic CYP system to generate the active metabolites that inhibit the P2Y₁₂ receptor.

The addition of clopidogrel to ASA was studied in the CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial of 12,562 patients with NSTEMI-ACS in which patients were treated with ASA, unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), and other standard therapies and were randomly assigned to receive a 300-mg loading dose of clopidogrel followed by 75 mg daily or placebo.⁸¹ The addition of clopidogrel to ASA reduced cardiovascular death, MI, or stroke by 20% in both low- and high-risk patients with NSTEMI-ACS, regardless of whether they were managed with medical therapy, PCI, or coronary artery bypass grafting (CABG) (Fig. 53-9). Benefit was seen as early as 24 hours, with Kaplan-Meier curves beginning to diverge after just 2 hours.⁸² Moreover, the benefit continued throughout the trial's 1-year treatment period. Benefit of treatment before PCI was also observed, with a 31% reduction in cardiac events at 30 days and 1 year in patients with NSTEMI-ACS randomly assigned to DAPT versus ASA alone.⁸³

These and similar findings in other trials led to a class IA recommendation in the American College of Cardiology/American Heart

Association (ACC/AHA) guidelines for clopidogrel treatment before PCI.⁸⁴ In patients undergoing CABG, those who had received clopidogrel within 5 days of surgery had an increased risk for major bleeding and the need for reoperation, which led to the recommendation that use of clopidogrel be discontinued at least 5 days before surgery, if possible.⁶

In NSTEMI-ACS, the initial loading dose of 300 to 600 mg clopidogrel is followed by a maintenance dose of 75 mg daily. Use of a 600-mg loading dose achieves a steady-state level of platelet inhibition after just 2 hours, more rapidly than the 300 mg dose. In the CURRENT OASIS 7 trial, high-dose clopidogrel (600-mg loading dose, 150-mg maintenance dose for 7 days, then 75 mg thereafter) did not reduce the composite of cardiovascular death, MI, or stroke in patients with NSTEMI-ACS, although it increased major bleeding and the need for red cell transfusions.⁷⁶ However, an analysis of the subgroup of patients in CURRENT OASIS-7 who underwent PCI⁸⁵ and a meta-analysis of more than 25,000 patients undergoing PCI⁸⁶ both demonstrated that a 600-mg loading dose of clopidogrel reduces cardiovascular events following PCI when compared with 300 mg. Thus 600 mg clopidogrel is the preferred loading dose for patients with NSTEMI-ACS undergoing PCI.^{75,84}

Two strategies for initiating clopidogrel therapy in patients with NSTEMI-ACS have evolved: (1) starting clopidogrel at the time of arrival or hospital admission or (2) delaying treatment with clopidogrel until after coronary angiography and then administering the drug on the catheterization table if PCI is performed. The early treatment strategy is preferred because it affords the benefits of reducing early ischemic events, albeit at the cost of an increase in bleeding in the minority of patients who undergo CABG instead of or immediately after PCI.⁸⁷

As with ASA, hyporesponders to clopidogrel have been identified⁸⁸ and have higher rates of recurrent cardiac events, including stent thrombosis, MI, and death.⁸⁹ The incidence of patients not achieving the expected pharmacologic response to clopidogrel varies from 5% to 30%, depending on the population and the definition used to assess response.⁸⁹ Hyporesponsiveness to clopidogrel is more common in patients with diabetes, as well as in those with obesity, of advanced age, and with a genetic polymorphism of the CYP system.⁹⁰ Patients

with a minimal antiplatelet response to clopidogrel have lower concentrations of the active metabolite, thus indicating failure of this necessary conversion.

Several polymorphisms of the gene encoding for the CYP2C19 enzyme have been associated with reduced production of the active metabolite of clopidogrel (see also Chapters 7, 52, and 82).⁶⁹ These polymorphisms (especially the reduced-function *C2 allele) occur in approximately a third of white individuals and up to half of Asians and have been associated with increased adverse clinical outcomes in patients treated with clopidogrel.⁹¹ In other studies, reduced-function alleles have been associated with increased stent thrombosis.⁹² Testing for these polymorphisms in patients who are candidates for thienopyridine treatment can identify those who are likely to be unresponsive or hyporesponsive to the standard dose of clopidogrel and are candidates for alternative antiplatelet regimens (Fig. 53-10). Three randomized trials that evaluated more aggressive antiplatelet regimens in patients with high platelet reactivity after standard doses of aspirin and clopidogrel, however, did not show a significant reduction in clinical cardiovascular events with higher doses of antiplatelet drugs versus standard doses.⁹³⁻⁹⁵ Data from a study of

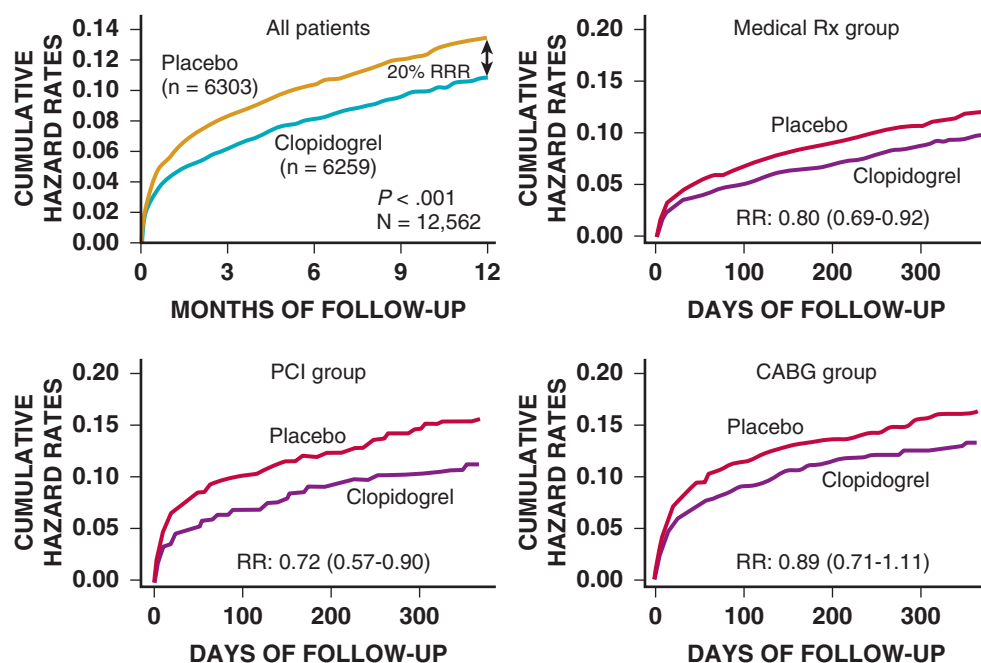

FIGURE 53-9 Clopidogrel for NSTEMI-ACS. The benefit of clopidogrel in reducing cardiovascular death, MI, or stroke in patients with NSTEMI-ACS in the CURE trial and in patients managed medically or with PCI or CABG is shown. RR = relative risk; Rx = drug. (From Yusuf S, Zhao F, Mehta SR, et al: Effects of clopidogrel in addition to aspirin in patients with acute coronary syndromes without ST-segment elevation. *N Engl J Med* 345:494, 2001; and Fox KA, Mehta SR, Peters R, et al: Benefits and risks of the combination of clopidogrel and aspirin in patients undergoing surgical revascularization for non-ST-elevation acute coronary syndrome: The Clopidogrel in Unstable angina to prevent Recurrent ischemic Events [CURE] trial. *Circulation* 110:1202, 2004.)

FIGURE 53-10 CYP2C19 and clinical outcomes. The association between status as a carrier of a CYP2C19 reduced-function allele and the primary efficacy outcome or stent thrombosis is shown in subjects receiving clopidogrel in the TRITON-TIMI 38 trial. Among 1459 subjects who were treated with clopidogrel and could be classified as CYP2C19 carriers or noncarriers, the rate of the primary efficacy outcome (a composite of death from cardiovascular [CV] causes, MI, or stroke) was significantly higher in carriers than in noncarriers. (From Mega JL, Close SL, Wiviott SD, et al: Cytochrome p-450 polymorphisms and response to clopidogrel. *N Engl J Med* 360:354, 2009.)

patients with UA undergoing PCI showed that a daily maintenance dose of 225 mg or more of clopidogrel (at least three times the standard dose) is necessary in heterozygote carriers of the CYP2C19*2 allele to achieve the same level of platelet inhibition as that in noncarriers who receive 75 mg daily.⁹⁶ Thus the reason that these three trials failed to show clinical benefit with more intensive antiplatelet regimens in patients with high platelet reactivity may be due in part to insufficiently high doses of antiplatelet therapy.

Proton pump inhibitors (PPIs) modestly reduce the antiplatelet effect of clopidogrel when assessed by platelet function assays⁹⁷ because of competition for metabolism by the CYP3A4 enzyme. Observational studies have raised concern that this effect may lead to ischemic complications in patients receiving such an inhibitor, especially omeprazole, as opposed to clopidogrel without a PPI. However, a randomized, double-blind trial⁹⁸ and an analysis of ticagrelor (which is not metabolized via the CYP system) versus clopidogrel⁹⁹ indicated that a clinically significant interaction between clopidogrel and PPIs is unlikely.

Prasugrel

This thienopyridine is a prodrug like clopidogrel, and its active metabolite is an irreversible inhibitor of the platelet P2Y₁₂ receptor and thereby an inhibitor of platelet aggregation. However, unlike clopidogrel, prasugrel is oxidized rapidly in one step to its active metabolite and becomes active within 30 minutes of ingestion. Although the active metabolites of clopidogrel and prasugrel exert equal antiplatelet effects when studied in vitro, generation of the prasugrel metabolite is approximately 10 times as great as generation of the clopidogrel metabolite, which results in roughly 10 times greater potency.

TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction)¹⁰⁰ randomly assigned 13,608 patients with ACS (10,074 with NSTEMI-ACS) in whom PCI was planned to receive either prasugrel (60-mg loading dose, 10-mg daily maintenance dose) or what was then the Food and Drug Administration (FDA)-approved dose of clopidogrel (300-mg loading dose, 75-mg daily maintenance dose)—which had been shown in the CURE trial to be beneficial in NSTEMI-ACS patients who underwent PCI. All patients also received ASA.⁸³ The primary efficacy endpoint (cardiovascular death, MI, and stroke) was reduced significantly by 19% with prasugrel (Fig. 53-11A).

The benefit was particularly striking (30%) in patients with diabetes.¹⁰¹ In the 12,844 patients who received coronary stents at the time of PCI, prasugrel reduced the incidence of stent thromboses by half in comparison to clopidogrel. This relative reduction in stent thrombosis was similar in bare-metal and drug-eluting stents.¹⁰²

These findings of the superiority of prasugrel over clopidogrel agrees with the aforementioned concept that the limited efficacy of clopidogrel versus prasugrel is related to the slower and less effective generation of the active metabolite of clopidogrel.¹⁰³ Indeed, in a crossover study of patients undergoing PCI for stable angina, Wiviott and coauthors reported that a 60-mg loading dose of prasugrel resulted in greater platelet inhibition than did a 600-mg loading dose of clopidogrel.¹⁰⁴ The same was observed during maintenance therapy, for which the comparison was made between 10 mg prasugrel and 150 mg clopidogrel daily.

Not unexpectedly, the greater platelet inhibitory effect of prasugrel was associated with increased bleeding. In TRITON-TIMI 38, there was a 0.6% absolute (32% relative) higher incidence of major (including fatal) bleeding. The risk for bleeding was especially high in elderly adults (≥75 years of age), in whom the use of prasugrel should be limited to those at high risk and in those with reduced body weight (<60 kg, 132 lb). Avoidance of treating such patients with prasugrel unless they are at high risk for thrombosis is advisable, and if prasugrel is used, they should be treated with a 5-mg instead of a 10-mg maintenance dose. Patients with a history of stroke or transient ischemic attack (TIA) have a prohibitive incidence of intracranial hemorrhage. Therefore prasugrel is indicated in patients with NSTEMI-ACS immediately before PCI but is contraindicated in those with a history of stroke or TIA.¹⁰⁰ In patients who were younger than 75 years, weighed at least 60 kg, and had no previous history of stroke or TIA (i.e., the “core” group of patients for whom the FDA approved use of the drug), prasugrel was associated with a robust 26% reduction in the primary endpoint. Use of prasugrel should be discontinued at least 7 days before surgery is performed, whenever possible.⁷⁵ DAPT with ASA and a P2Y₁₂ receptor inhibitor should be continued for 1 year following PCI.

Prasugrel (10 mg daily) was compared with clopidogrel (75 mg daily) in 7243 patients younger than 75 years who were being managed medically following NSTEMI-ACS in the TRILOGY ACS (Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes) trial.¹⁰⁵ No difference occurred in the primary composite endpoint of cardiovascular death, MI, or stroke, nor in severe bleeding.

Ticagrelor

In contrast to the thienopyridines, whose active metabolites are irreversible platelet inhibitors, ticagrelor is a reversible blocker of the P2Y₁₂ platelet receptor that acts directly on the platelet and has a half-life of approximately 12 hours.¹⁰⁶ Although it has an active metabolite, the potency of the latter is similar to that of the parent drug; both are excreted into bile. Like prasugrel, ticagrelor can inhibit P2Y₁₂-mediated platelet aggregation almost completely.

A phase III pivotal trial (PLATO) compared ticagrelor (180-mg loading dose, followed by 90 mg twice daily) with clopidogrel (a 300- or 600-mg loading dose, followed by a 75-mg daily maintenance dose); both groups also received ASA. The PLATO trial enrolled 18,624 patients, 11,067 (59%) of whom had NSTEMI-ACS.¹⁰⁶ The primary endpoint, a composite of cardiovascular death, MI, and stroke, fell significantly by 16% (Fig. 53-11B). A significant 16% reduction in MI, a 21% reduction in cardiovascular death, and a 22% relative (1.4% absolute) reduction in total mortality also occurred. The rate of stent thrombosis was reduced significantly, from 1.9% to 1.3%. A broad array of subgroups showed greater clinical efficacy of ticagrelor than clopidogrel, including those who had previously received clopidogrel, in patients treated with a noninvasive strategy, as well as in patients with STEMI.

PLATO showed no benefit of ticagrelor in the subgroup of patients enrolled in the United States, in whom the dose of aspirin was higher on average than in other countries.⁷⁷ Whether this finding is related to chance, to more frequent use of ASA at 325 mg daily, or to some

other aspect of care in the United States remains uncertain. The FDA has recommended that low-dose (75 to 100 mg) ASA be used for maintenance with ticagrelor. Regardless of which P2Y₁₂ inhibitor is selected as the second antiplatelet agent, the dose of aspirin should be decreased to 75 to 100 mg after the initial loading dose, and patients should be monitored for bleeding while receiving DAPT for 1 year following NSTEMI-ACS.⁷⁵ PLATO showed a 0.7% absolute (19% relative) higher incidence of non-CABG-related major bleeding ($P = 0.03$) with ticagrelor than with clopidogrel. Episodes of moderate or minor dyspnea and ventricular pauses exceeding 5 seconds occurred more frequently in patients treated with ticagrelor than in those treated with clopidogrel.

The PLATO investigators calculated that if 1000 hospitalized patients with ACS were treated with ticagrelor and ASA and compared with a similar group treated with clopidogrel and ASA, there would be 14 fewer deaths, 11 fewer MIs, 6 to 8 fewer cases of stent thrombosis, and 7 more patients with non-CABG-related major bleeding, with 9 patients switching to a thienopyridine because of dyspnea. Because ticagrelor is a reversible agent, it can be started at the time of arrival at the emergency department and be continued

for 1 year in medically managed patients or those undergoing PCI.⁷⁵ Although ticagrelor achieves a higher level of platelet inhibition than clopidogrel does, it has a shorter effective half-life and should be discontinued 5 days before CABG.⁷⁵ However, the shorter half-life mandates twice-daily administration of this drug and may therefore reduce compliance.

Protease-Activated Receptor-1 Antagonists

The oral protease-activated receptor-1 (PAR-1) antagonist vorapaxar, an investigational drug that inhibits thrombin-mediated platelet activation, has been studied in patients with ACS. It did not reduce the primary efficacy endpoint significantly, but major bleeding was increased, including intracranial hemorrhage.¹⁰⁷ Thus vorapaxar does not appear to have a role early after ACS. In the TRA-2P-TIMI 50 (Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events—Thrombolysis in Myocardial Infarction) trial of 26,449 stable patients with a history of MI, ischemic stroke, or peripheral vascular disease, the addition of vorapaxar to standard therapies reduced ischemic events while increasing bleeding in comparison to placebo.¹⁰⁸ Patients 2 weeks to 1 year after MI who were enrolled in TRA-2P had a 20% reduction in cardiovascular death, MI, or stroke. The drug may thus play a role in secondary prevention in patients with NSTEMI.

Glycoprotein IIb/IIIa Inhibitors

These drugs block the final common pathway of platelet aggregation, fibrinogen-mediated cross-linkage of platelets, caused by a variety of stimuli (e.g., thrombin, ADP, collagen, serotonin) (see Fig. 53-3). Three agents in this class are available: abciximab, a monoclonal antibody approved only in patients undergoing PCI; eptifibatide; and tirofiban (the latter two are reversible small-molecule inhibitors). Each of these agents is administered as an intravenous bolus followed by continuous infusion. The activity of the small-molecule receptor blockers and the accompanying bleeding risk subside promptly after discontinuation of the infusion. Tirofiban and eptifibatide have short half-lives (≈ 2 hours), with restoration of platelet function in about 4 hours; thus they should be discontinued 2 to 4 hours before major surgery. Abciximab has prolonged action (≈ 12 hours) and cannot be reversed rapidly, so major surgery should be deferred until at least 24 hours after administration.

Several trials have shown benefit of GP IIb/IIIa inhibition in the management of patients with NSTEMI-ACS, with an overall significant 9% relative reduction in death or MI at 30 days in a large meta-analysis.¹⁰⁹ Tirofiban plus heparin and aspirin significantly reduced the rate of death, MI, or refractory ischemia at 7 days when compared with heparin plus ASA.¹¹⁰ In a trial involving 10,948 patients, eptifibatide also significantly reduced the rate of death or MI at 30 days.¹¹¹ However, no benefit and higher early mortality were found with the use of abciximab in patients with NSTEMI-ACS in whom an early conservative strategy was planned.¹¹²

The benefit of GP IIb/IIIa inhibition appears to be greater when used in high-risk patients with NSTEMI-ACS, such as those with ST-segment changes and/or elevated troponin concentration or diabetes.^{109,113} These subgroups have more thrombus at coronary angiography and thus have higher risk for microvascular embolization. The benefit of GP IIb/IIIa inhibition has been confirmed even in patients with a background of clopidogrel pretreatment.^{113,114}

In a meta-analysis of placebo-controlled trials, rates of major hemorrhage were significantly higher in patients treated with GP IIb/IIIa inhibitors—occurring in 2.4% as opposed to 1.4% of those given placebo.¹⁰⁹ The rate of severe thrombocytopenia ($<50,000/\text{mm}^3$) was approximately 0.5% in patients treated with a GP IIb/IIIa

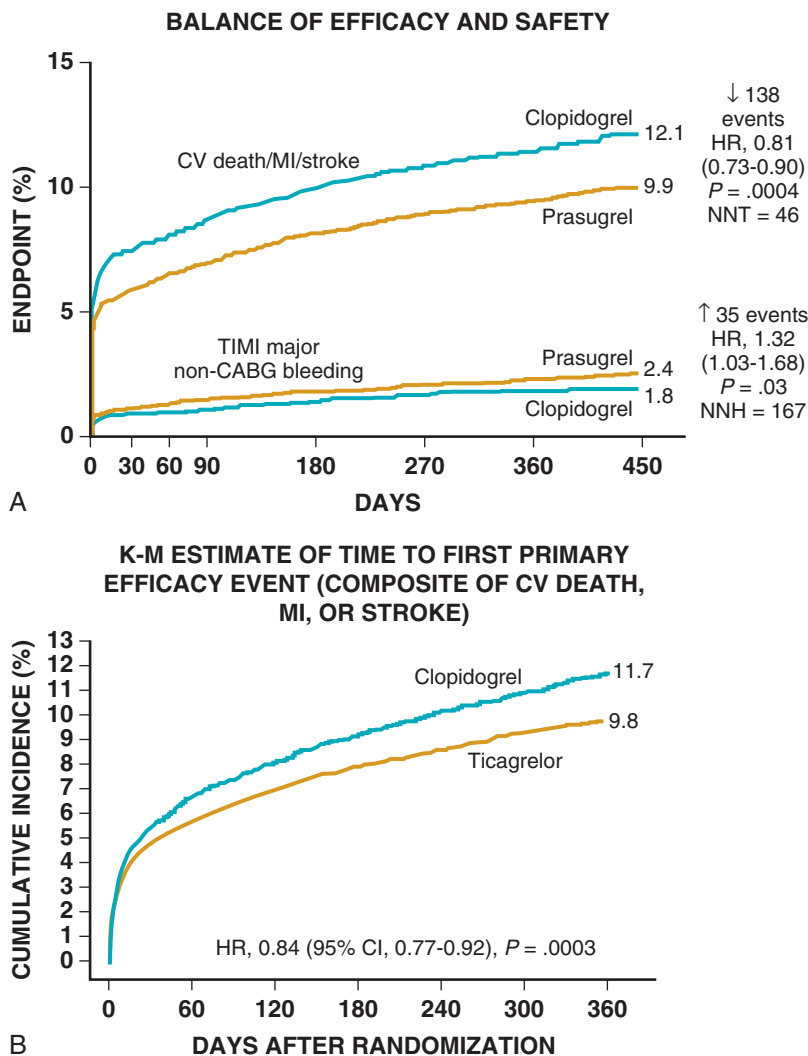

FIGURE 53-11 **A**, Comparison of the efficacy and safety of prasugrel versus clopidogrel in the TRITON-TIMI 38 trial in patients with ACSs undergoing PCI. HR = hazard ratio; NNT = number of patients needed to prevent one primary endpoint event; NNH = number of patients needed to be treated to cause harm (TIMI major bleeding). **B**, The primary endpoint of the PLATO trial—a composite of death from vascular causes, MI, or stroke—occurred significantly less often in the ticagrelor group than in the clopidogrel group. CV = cardiovascular; KM = Kaplan-Meier. (**A**, From Wiviott SD, Braunwald E, McCabe CH, et al: Prasugrel versus clopidogrel in patients with acute coronary syndromes. *N Engl J Med* 357:2001, 2007; **B**, from Wallentin L, Becker RC, Budaj A, et al: Ticagrelor versus clopidogrel in patients with acute coronary syndromes. *N Engl J Med* 361:1045, 2009.)

inhibitor and heparin versus 0.3% in those receiving heparin alone. Thrombocytopenia is associated with increased bleeding and recurrent thrombotic events, thus indicating a need to monitor the platelet count daily during the GP IIb/IIIa infusion.

Two large trials have examined the timing of initiation of GP IIb/IIIa inhibitors: routine early administration at initial evaluation versus delayed provisional use just before PCI.^{115,116} No difference was seen in the primary efficacy outcome between these two strategies, although routine early administration of GP IIb/IIIa inhibitors was associated with an increased risk for bleeding. A meta-analysis of 12 clinical trials involving 46,374 patients with NSTEMI-ACS treated with a GP IIb/IIIa inhibitor at initial encounter and before angiography demonstrated a significant 11% reduction in death or MI at 30 days versus control patients (either no GP IIb/IIIa inhibitor or deferred use just before PCI), although the benefit of early routine use appeared to be modest when compared with a strategy of deferred use before PCI.¹¹⁷ Furthermore, there was no reduction in mortality and a 23% relative increase in major bleeding with routine early use of GP IIb/IIIa inhibitors.

Based on the totality of the evidence, a strategy of routine administration of GP IIb/IIIa inhibitors to patients with NSTEMI-ACS who receive DAPT with ASA and a P2Y₁₂ inhibitor (i.e., triple antiplatelet therapy) is not recommended. However, selective use in patients at high risk for ischemic complications (such as patients with diabetes or angiographic evidence of thrombus) and at low risk for bleeding who are to undergo PCI appears to be more prudent. GP IIb/IIIa inhibitors are also useful in the management of thrombotic complications during PCI.

Anticoagulant Therapy

In addition to antiplatelet therapy, as described above, an anticoagulant should be administered to patients with NSTEMI-ACS as soon as possible. Several anticoagulants are available (see [Chapter 82](#)).

Heparin

UFH is a mixture of polysaccharide chains of different length that prevents coagulation by blocking thrombin (factor IIa) and factor Xa. It also binds to circulating plasma proteins, acute-phase reactants, and endothelial cells and thus has an unpredictable anticoagulant effect. Because of its short half-life, UFH must be administered as an intravenous infusion to ensure a stable level of anticoagulation in patients with ACS.

Despite these limitations, treatment with intravenous UFH has been an important component of therapy for patients with NSTEMI-ACS.¹¹⁸ A meta-analysis showed a 33% reduction in death or MI with UFH plus aspirin versus aspirin alone.¹¹⁹ Variability in the anticoagulant effects of UFH, which is quite common, is thought to result from the heterogeneity of UFH and from neutralization of heparin by circulating plasma factors and by proteins released by activated platelets.¹²⁰ Daily monitoring of the anticoagulant response via the activated partial thromboplastin time (APTT) is recommended, with titrations being made according to a standardized nomogram to achieve an APTT of 50 to 70 seconds or 1.5 to 2.5 times control.⁶⁵ Based on the data available, the ACC/AHA guidelines recommend a weight-adjusted dose of UFH (60-unit/kg bolus and 12-unit/kg/hr infusion), as well as frequent monitoring of the APTT (every 6 hours until the target range is reached and every 12 to 24 hours thereafter) and adjustment of the dose if necessary.⁷⁵ Adverse effects include bleeding, especially when the APTT is elevated. Immunogenic heparin-induced thrombocytopenia (HIT) is an infrequent but serious complication that can cause thrombosis and bleeding and may even be fatal.

Heparin Reversal

Protamine sulfate binds heparin to form a stable salt, thus quickly reversing the anticoagulant effect of UFH. Approximately 1 mg of protamine is required to neutralize 100 units of UFH. Because the half-life of UFH is approximately 1 to 1.5 hours, the dose of protamine necessary to reverse an infusion of UFH should be based on the total UFH dose administered in the previous 2 to 3 hours. After

administration of protamine, the APTT can be used to assess the efficacy of reversal of the anticoagulant effect of UFH. A slow intravenous injection is recommended to avoid hypotension or bradycardia. Other common, but transient adverse reactions include flushing, feeling of warmth, and dyspnea. Protamine reverses approximately 60% of the anticoagulant effect of LMWH (see below) but does not completely neutralize its anti-Xa activity.

Low-Molecular-Weight Heparin

These forms of heparin are enriched with shorter polysaccharide chains, which results in a more predictable anticoagulant effect than that of UFH. LMWH has several potential advantages over UFH: (1) its greater anti-factor Xa activity (relative to factor IIa) inhibits thrombin generation more effectively; (2) LMWH induces greater release of tissue factor pathway inhibitor than UFH does, and it is not neutralized by platelet factor 4; (3) LMWH less frequently causes HIT¹²¹; (4) the high and consistent bioavailability of LMWH allows subcutaneous administration; (5) monitoring of the anticoagulation level is not necessary; and (6) LMWH binds less avidly to plasma proteins than UFH does and therefore has a more consistent anticoagulant effect.

Because renal dysfunction affects LMWH more than UFH, the dose of LMWH should be reduced in patients with a creatinine clearance lower than 30 mL/min. The standard dose of enoxaparin is 1 mg/kg subcutaneously every 12 hours, with dosing only once daily for patients with a creatinine clearance lower than 30 mL/min. Administration of enoxaparin for up to 8 days (or until hospital discharge) was found to be effective in patients with ACS, whereas extending therapy to 6 weeks did not further reduce ischemic events in patients with NSTEMI-ACS.¹²² UFH should not be administered in the catheterization laboratory within 10 hours of treatment with enoxaparin, 1 mg/kg, unless factor Xa activity is known to be low because concomitant administration of UFH can result in supratherapeutic anti-Xa and anti-IIa levels and cause excess bleeding.¹²³ In the event of bleeding, the anticoagulant effect of LMWH can be reversed with protamine, but less effectively than reversal of UFH (see above).

In patients with NSTEMI-ACS treated with ASA, LMWH reduced the odds of death or MI by 66% when compared with placebo.¹¹⁹ Although several LMWHs have been approved, the weight of evidence supports the choice of enoxaparin.^{6,65} In a meta-analysis of 21,945 patients from six trials of patients with NSTEMI-ACS in which enoxaparin was compared with UFH, however, new or recurrent MI occurred less frequently with enoxaparin, whereas the rate of major bleeding was similar between the drugs.¹²⁴

Direct Thrombin Inhibitors

These drugs have a potential advantage over indirect thrombin inhibitors such as UFH or LMWH in that they do not require antithrombin and can inhibit clot-bound thrombin. They do not interact with plasma proteins, they provide a very stable level of anticoagulation, and they do not cause thrombocytopenia—thus making them an excellent choice for anticoagulation in patients with a history of HIT.

Bivalirudin, the most widely used direct thrombin inhibitor in patients with ACS or undergoing PCI, binds reversibly to thrombin and has a half-life of approximately 25 minutes. In the ACUITY (Acute Catheterization and Urgent Intervention Triage Strategy) trial,¹²⁵ patients with NSTEMI-ACS managed with an early invasive strategy were randomly assigned in an open-label fashion to one of three treatments: (1) UFH or enoxaparin with or without a GP IIb/IIIa inhibitor, (2) bivalirudin with a GP IIb/IIIa inhibitor, and (3) bivalirudin alone. The key findings were that bivalirudin alone reduced bleeding in comparison to either strategy that included a GP IIb/IIIa inhibitor; there were no differences in major bleeding between anticoagulants (UFH or enoxaparin versus bivalirudin) in patients taking a GP IIb/IIIa inhibitor, and there were no differences in ischemic events between the three treatment arms.¹²⁵ Thus the use of bivalirudin monotherapy (with ASA and a P2Y₁₂ inhibitor but without a GP IIb/IIIa inhibitor) is now considered an acceptable alternative in patients with NSTEMI-ACS managed with an early invasive strategy and may be preferred in patients with increased risk for bleeding who are undergoing PCI.^{6,65,75}

In patients with NSTEMI-ACS before angiography, the recommended dose of bivalirudin is a 0.1-mg/kg intravenous bolus followed by an infusion at 0.25 mg/kg/hr. If started during the procedure, a 0.75-mg/kg bolus dose of bivalirudin should be administered, followed by an infusion at 1.75 mg/kg/hr during PCI. It may be discontinued shortly after PCI to permit removal of arterial access sheaths. In patients with renal dysfunction, the infusion should be modified as follows: (1) if the creatinine clearance is lower than 30 mL/min and the patient is not being managed with hemodialysis, the infusion rate should be reduced to 1 mg/kg/hr, and (2) in patients undergoing hemodialysis, the infusion rate should be reduced to 0.25 mg/kg/hr.

Factor Xa Inhibitors

Fondaparinux

This synthetic pentasaccharide is an indirect Xa inhibitor and requires the presence of antithrombin for its action. The OASIS-5 trial compared daily subcutaneous fondaparinux (2.5 mg) with standard-dose enoxaparin in 20,078 patients with high-risk NSTEMI-ACS.¹²⁶ No difference was found in the primary ischemic composite through 9 days, although fondaparinux did reduce major bleeding by nearly half and mortality at 30 days tended to be lower with fondaparinux. In patients undergoing PCI, however, fondaparinux was associated with more than a threefold increased risk for catheter-related thrombi. Supplemental UFH at the time of catheterization (85 units/kg if no GP IIb/IIIa inhibitor was used; 60 units/kg with a concomitant GP IIb/IIIa inhibitor) appeared to minimize the risk for this problem with fondaparinux.¹²⁷ Thus fondaparinux is an alternative for patients with NSTEMI-ACS managed noninvasively and, in particular, for patients at higher risk for bleeding.^{6,65}

Otamixaban

At infusions of 0.105 and 0.140 mg/kg/hr, the investigational direct factor Xa inhibitor otamixaban is associated with fewer ischemic complications and similar safety as UFH plus eptifibatide in patients with ACS.¹²⁸ A large phase III trial of otamixaban is under way.¹²⁹

Oral Anticoagulation

Several trials have examined oral anticoagulation with warfarin following ACS because of the rationale that prolonged treatment might extend the benefit of early anticoagulation with a parenteral antithrombin agent. Although the combination of ASA plus warfarin was more effective than aspirin alone for long-term secondary prevention of MI, this combination is associated with increased serious bleeding.¹³⁰ In patients without a coronary stent but with another indication for warfarin, such as chronic atrial fibrillation or severe left ventricular dysfunction, who are at high risk for systemic embolization, the combination of ASA and warfarin may be useful for long-term antithrombotic management.

Triple therapy (i.e., the combination of aspirin, a P2Y₁₂ inhibitor, and warfarin) is sometimes required in patients with NSTEMI-ACS after stenting who have atrial fibrillation or another strong indication for warfarin. It may be associated with a high bleeding risk, especially with long-term administration,¹³¹ but it has not been tested prospectively to date against DAPT in a large randomized trial. When such triple therapy is deemed essential, the combination of low-dose aspirin (75 to 81 mg daily), warfarin (titrated meticulously to an international normalized ratio [INR] of 2.0 to 2.5), and the use of clopidogrel for as short a time as necessary is recommended.⁶ Use of bare-metal stents rather than drug-eluting stents may be preferable because they can reduce the duration of P2Y₁₂ therapy required. The 2010 European Society of Cardiology (ESC) guidelines for the management of patients with atrial fibrillation in whom NSTEMI-ACS has been treated with a stent recommend shortened courses of triple therapy (aspirin, clopidogrel, a vitamin K antagonist [VKA]), followed by long-term single antiplatelet therapy and a VKA.¹³²

Two potent oral direct factor Xa inhibitors (rivaroxaban and apixaban) have been studied in phase III trials of patients with ACS. In the ATLAS ACS 2-TIMI 51 (Anti-Xa Therapy to Lower Cardiovascular Events in Addition to Standard Therapy in Subjects with Acute Coronary Syndrome—Thrombolysis in Myocardial Infarction) trial,

FIGURE 53-12 Rivaroxaban and cardiovascular mortality after ACS. The cumulative incidence of cardiovascular death is shown in patients after ACS who received aspirin and a thienopyridine and were randomly assigned to placebo (n = 5114) versus rivaroxaban, 2.5 mg twice daily (n = 5113). (Modified from Mega JL, Braunwald E, Wiviott SD, et al: Rivaroxaban in patients with a recent acute coronary syndrome. *N Engl J Med* 366:9, 2012.)

low-dose rivaroxaban (5 mg twice daily) and very low-dose rivaroxaban (2.5 mg twice daily)—which are 50% and 25%, respectively, of the approved dose of this drug in patients with atrial fibrillation—were compared with placebo as an add-on to standard DAPT therapy (ASA and clopidogrel in 92% of patients) in 15,527 patients with recent ACS.¹³³ Rivaroxaban (doses combined) reduced the primary composite of death, MI, or stroke significantly by 16% when compared with antiplatelet therapy without an anticoagulant. In addition, rivaroxaban substantially reduced overall mortality and stent thrombosis, although excessive bleeding, including higher rates of intracerebral hemorrhage, were observed. The 2.5-mg twice-daily dose of rivaroxaban had a more favorable profile in that it reduced cardiovascular mortality (Fig. 53-12) by 34% and total mortality by 32% and resulted in less bleeding than the 5 mg twice-daily dose of rivaroxaban.

In the APPRAISE-2 (Apixaban for Prevention of Acute Ischemic Events 2) trial,¹³⁴ apixaban, 5 mg twice daily (a full dose of Xa inhibitor with properties similar to those of rivaroxaban), was compared with placebo in 7392 patients with recent ACS (60% had NSTEMI-ACS) who were being treated with aspirin and clopidogrel. The trial was stopped prematurely because of excess major bleeding with no apparent reduction in recurrent ischemic events in patients randomly assigned to apixaban. The difference in outcome between APPRAISE-2 and ATLAS-2-TIMI 51 might be related to the higher dose of the Xa inhibitor in APPRAISE-2; in contrast to ATLAS-2-TIMI 51, it included patients with a history of stroke.

Bleeding—Risk Assessment, Prevention, and Treatment

Severe bleeding is the most common nonischemic complication of antithrombotic therapy and is associated with poorer outcomes in patients with ACS,¹³⁵ but controversy has surrounded the independent contribution of bleeding to mortality.^{136,137} Whether the increase in mortality and other adverse events observed in patients who have had serious bleeding is a result of the bleeding per se or the higher risk for adverse outcomes from the ACS in patients who are more likely to experience bleeding is unclear. Both mechanisms probably contribute.

Regardless, strong effort must be made to minimize bleeding. European guidelines⁶⁵ recommend assessment of bleeding risk (as well as risk for ischemia) in all patients with NSTEMI-ACS via an established risk score (Table 53-4).¹³⁸ Practical steps to reduce the risk for bleeding in patients with NSTEMI-ACS include the use of (1) weight-adjusted (instead of fixed) doses of anticoagulants; (2) modified dosing of antithrombotics in patients with renal dysfunction; (3) selection of

TABLE 53-4 CRUSADE Bleeding Risk Score for Estimating In-Hospital Risk for Major Bleeding

PREDICTOR	SCORE	PREDICTOR	SCORE
Baseline Hematocrit (%)		Signs of Congestive Heart Failure at Initial Evaluation	
≤31	9	No	0
31-33.9	7	Yes	7
34-36.9	3	Previous Vascular Disease [†]	
37-39.0	2	No	0
≥40	0	Yes	6

≤15	39	No	0
>15-30	35	Yes	6
>30-60	28	Systolic Blood Pressure (mm Hg)	
>60-90	17	<90	10
>90-120	7	91-100	8
>120	0	101-120	5
Heart Rate (beats/min)		121-180	1
≤70	0	181-200	3
71-80	1	≥201	5
81-90	3	RISK FOR BLEEDING	
91-100	6	Total Score (Range, 1-100) Predicted Risk for Bleeding (%)	
101-110	8	≤20 (very low)	3.1
111-120	10	21-30 (low)	5.6
≥121	11	31-40 (moderate)	8.6
Sex		41-50 (high)	13.4
Male	0	≥50 (very high)	22.6
Female	8		

*Creatinine clearance was estimated with the Cockcroft-Gault formula.

[†]Previous vascular disease was defined as a history of peripheral artery disease or previous stroke. To calculate the CRUSADE bleeding score, total the points associated with the above eight factors and use the bottom part of the table to predict the risk for bleeding.

[‡]In patients managed by an invasive strategy.

Modified from Giugliano RP, Braunwald E: The year in non-ST-segment elevation acute coronary syndrome. *J Am Coll Cardiol* 54:1544, 2009; modified from Subherwal S, Bach RG, Chen AY, et al: Baseline risk of major bleeding in non-ST-segment-elevation myocardial infarction: The CRUSADE (Can Rapid risk stratification of Unstable angina patients Suppress ADverse outcomes with Early implementation of the ACC/AHA guidelines) bleeding score. *Circulation* 119:1873, 2009.

anticoagulants with a lower-risk bleeding profile (e.g., fondaparinux in patients managed conservatively, bivalirudin with an early invasive strategy) in patients at higher bleeding risk; (4) low-dose aspirin (75 to 100 mg daily) after the initial loading dose⁷⁶; (5) gastrointestinal protective agents in patients at high risk for gastrointestinal bleeding⁹⁸; (6) minimization of concomitant therapies (such as nonsteroidal anti-inflammatory drugs) that increase the risk for gastrointestinal bleeding; (7) radial arterial access, smaller sheath sizes, and timely removal of sheaths for coronary angiography and PCI¹³⁹; and (8) use of bare-metal (instead of drug-eluting) stents, which permits a shorter course of DAPT (1 month instead of 6 to 12 months).

Among the key recommendations included in the Working Group on Thrombosis of the ESC¹⁴⁰ are (1) interruption and/or neutralization of antithrombotic therapy in the case of major bleeding, unless adequate hemostasis is achieved by other specific measures; (2) withholding of transfusions in stable patients with a hemoglobin level higher than 8 g/dL if bleeding has stopped; and (3) continuation of antithrombotic therapy without interruption in the case of minor bleeding.

Invasive Versus Conservative Management

Two general approaches to the use of cardiac catheterization and revascularization can be taken in patients with NSTEMI-ACS: (1) an early invasive strategy involving routine early (within 48 hours of initial evaluation) cardiac catheterization, followed by PCI, CABG, or

continuing medical therapy, depending on the coronary anatomy, and (2) a more conservative approach, with initial medical management and catheterization being reserved for patients with recurrent ischemia either at rest or on a noninvasive stress test, followed by revascularization if the anatomy is suitable.

A meta-analysis of seven recent trials confirmed an overall significant 25% reduction in mortality and a 17% reduction in nonfatal MI after 2 years of follow-up in patients managed with an early invasive strategy.¹⁴¹ These findings favoring an early invasive strategy were also observed in key subgroups who traditionally are less likely to undergo early angiography, including older adults,^{142,143} patients with CKD,¹⁴⁴ and women,¹⁴⁵ although one analysis in women did not show benefit.¹⁴⁶ The apparently conflicting results in women may be reconciled by considering the risk of the women who were included in the studies inasmuch as a sex-specific collaborative meta-analysis¹⁴⁷ demonstrated benefit of an invasive strategy in all men and in high-risk women but not in low-risk women.

Thus an early invasive strategy is recommended in patients with NSTEMI-ACS who have ST-segment changes and/or positive troponin on admission or in whom these high-risk features develop over the subsequent 24 hours. Other high-risk indicators, such as recurrent ischemia or evidence of congestive heart failure, are indications for an early invasive strategy.^{6,65,75} An early invasive strategy is also advised in patients with NSTEMI-ACS previously treated with CABG⁶ and in patients who have had NSTEMI-ACS within 6 months of a previous PCI and in whom restenosis may be the cause.⁶⁵ Indications for an initial

conservative strategy include patients with life-threatening comorbid conditions or in whom the risks outweigh the benefits, patients who do not wish to undergo an invasive procedure, and low-risk patients without recurrent symptoms.^{65,75}

Timing of an Invasive Approach

A meta-analysis of four trials involving 4013 patients with NSTEMI-ACS compared an early invasive strategy (average time to angiography ranging from 1.2 to 14 hours) with a delayed invasive strategy (average time to angiography of 21 to 86 hours). Mortality and MI rates in the two strategies did not differ,¹⁴⁸ but the early invasive approach was associated with significant reductions in recurrent ischemia (41%) and duration of hospital stay (28%) and with favorable trends with respect to bleeding and the composite of cardiovascular death, MI, or stroke. This analysis lends support to an early invasive strategy, especially in high-risk patients such as those with continuing ischemia despite intensive medical therapy, as well as in patients with acute heart failure and ventricular tachyarrhythmias.

Percutaneous Coronary Intervention (See Chapter 55)

Angiographic success (TIMI epicardial grade 2 or 3 flow) can be achieved in the vast majority (95%) of patients with NSTEMI-ACS who undergo PCI, even in those considered to be at high risk.¹⁴⁹ However, the development of intraprocedural complications, such as transient or sustained loss of a side branch, abrupt closure, distal embolization, or development of the no-reflow phenomenon, has been associated with a fourfold to fivefold increase in the risk for ischemic complications and death over the next 30 days.^{149,150} Use of GP IIb/IIIa inhibitors improves acute outcomes following PCI. Although use of a drug-eluting stent reduces the risk for restenosis, there is a risk for late stent thrombosis following implantation of a drug-eluting stent, especially when DAPT (i.e., ASA and a P2Y₁₂ inhibitor) is discontinued. This serious complication can be reduced in the long term (at least 6 to 12 months) in patients treated with drug-eluting stents.

The third-generation stents coated with everolimus have demonstrated consistent benefits in comparison to earlier-generation stents coated with sirolimus or paclitaxel^{151,152} and in comparison to bare-metal stents.¹⁵³ Given reductions in stent thrombosis and other ischemic events following placement of an everolimus-eluting stent, the need for prolonged (≥ 12 months) DAPT is less clear, and shorter durations of DAPT may be possible.¹⁵⁴

Percutaneous Coronary Intervention Versus Coronary Artery Bypass Grafting

Several trials have compared PCI and CABG in patients with ischemic heart disease, many of whom had NSTEMI-ACS. Based on the results, CABG is recommended for patients with disease of the left main coronary artery, as well as for those with multivessel disease (involving all three major epicardial vessels or the proximal left anterior descending artery plus a second artery) and a left ventricular ejection fraction lower than 40% and/or diabetes mellitus. In a recent study of 1900 patients with diabetes and multivessel CAD (27% of whom had NSTEMI-ACS), CABG significantly reduced the composite endpoint of death, MI, or stroke in comparison to PCI.¹⁵⁵ However, as experience with multivessel and left main PCI grows, an increasing number of nondiabetic patients with this more complex coronary anatomy may also be suitable for PCI. For other patients with less severe CAD, PCI is ordinarily performed if the coronary anatomy is suitable. PCI is associated with slightly lower initial morbidity and mortality and lower rates of stroke¹⁵⁵ than CABG is, but a higher need for repeated PCI¹⁵⁵⁻¹⁵⁷ and somewhat less relief of angina.¹⁵⁸

Lipid-Lowering Therapy

Long-term treatment with lipid-lowering therapy, especially with statins, has shown benefit in patients following acute MI and NSTEMI-ACS (see also Chapters 42 and 45).¹⁵⁹ In a prespecified subgroup of more than 3200 patients with UA in the LIPID (Long-Term Intervention with Pravastatin in Ischemic Disease) trial, pravastatin therapy led to a significant 26% reduction in total mortality.¹⁶⁰ Initiation of

FIGURE 53-13 Effect of intensive statin therapy following NSTEMI-ACS. The benefit of intensive statin therapy initiated early after ACS in the PROVE IT-TIMI 22 trial is shown. A significant reduction in events occurred in the first 30 days. (From Ray KK, Cannon CP, Cairns R, et al: The timing of benefits of intensive statin therapy in ACS: A PROVE IT-TIMI 22 substudy. *J Am Coll Cardiol* 46:1405, 2005.)

statins in the hospital at the time of an ACS has been associated with long-term benefits in outcome when compared with placebo.¹⁶¹

In the PROVE IT-TIMI 22 (Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction 22) trial, conducted in 4162 patients who were enrolled an average of 7 days following an ACS, intensive lipid-lowering therapy with atorvastatin, 80 mg, versus moderate lipid-lowering therapy with pravastatin, 40 mg (Fig. 53-13), resulted in a 16% reduction (median LDL levels achieved in the two arms were 62 and 95 mg/dL, respectively) in the primary endpoint (a composite of cardiovascular death, MI, stroke, revascularization, or unstable angina leading to hospitalization) and a 25% reduction in death, MI, or urgent revascularization.¹⁶² Benefits began to emerge only 2 weeks after random assignment,¹⁶³ thus highlighting the importance of early initiation of intensive statin therapy after ACS. Based in part on these results, the National Cholesterol Education Program (NCEP) recommended an optional therapeutic LDL goal of less than 70 mg/dL in high-risk patients with CHD, such as those with a history of an ACS.¹⁶⁴ Regression of CAD after ACS was observed with intensive lipid-lowering therapy in diabetic patients with NSTEMI-ACS when LDL lower than 70 mg/dL was achieved.¹⁶⁵

Four additional trials of intensive versus moderate (standard) statin therapy followed PROVE IT-TIMI 22, one involving post-ACS patients and three involving patients with stable CAD. A meta-analysis of the five published trials, including 39,612 patients monitored for a median of 5.1 years, showed highly significant reductions of 15% in major vascular events and a 13% reduction in coronary death or MI with intensive versus standard statin therapy.¹⁶⁶ Of note, no adverse effects of ultra-low LDL (below 40 to 50 mg/dL) have emerged,¹⁶⁷ and thus statin doses should not be routinely titrated downward in asymptomatic patients who are tolerating high-dose statins after ACS.

Intensive statin therapy for patients with an ACS should start, at the latest, at the time of hospital discharge,⁶ but benefit of intensive statin therapy before PCI with a 44% reduction in both peri-PCI MI and other adverse events through 30 days was demonstrated in a meta-analysis of 13 randomized trials¹⁶⁸—thus suggesting a benefit if high-dose statin therapy is started at the time of admission. Although epidemiologic studies have shown that patients with higher HDL cholesterol levels have a lower incidence of CHD, no pharmacologic therapies directed at raising HDL have yet demonstrated an improvement in clinical outcomes in patients with or after ACS in the statin era (see also Chapters 42 and 45).

Discharge and Posthospital Care

The time of hospital discharge following ACS affords a “teachable moment” for the patient,¹⁶⁹ when the physician and staff can review and optimize the medical regimen for long-term treatment. Patients

with NSTEMI-ACS and those with STEMI should receive secondary prevention approaches as described in **Chapters 42, 47, and 52**.

SUBGROUPS OF SPECIAL INTEREST

Older Adults

The incidence of ACS increases with age, and given the current demographic trends, elderly patients (≥ 75 years of age) will represent an increasing proportion of those with ACS. Yet evidence-based therapies are underused in older as opposed to younger patients,¹⁷⁰ even when considering comorbid conditions and contraindications.¹⁷¹

Elderly patients with NSTEMI-ACS present challenges to diagnosis and management, including a greater likelihood of atypical symptoms (e.g., dyspnea, confusion); noncoronary cause of ACS, such as hypertension, myocardial hypertrophy, and diastolic dysfunction; hepatic and renal dysfunction resulting in impaired metabolism and decreased clearance of drugs; and comorbid conditions that predispose to adverse reactions, such as bleeding and renal failure and higher risk for ischemic complications.¹⁷² The combination of these comorbid conditions and a greater tendency to use polypharmacy in older adults increases the risk for drug-drug interactions and side effects.

In general, pharmacologic treatment of NSTEMI-ACS in older adults should parallel the recommended therapies for younger patients, albeit with greater anticipation of and surveillance for adverse drug events.¹⁷³ The high prevalence of reduced renal function in elderly individuals, despite an apparently “normal” serum creatinine level, may lead to excess dosing of antithrombotics such as enoxaparin and GP IIb/IIIa inhibitors.¹⁷⁴ Guidelines recommend assessment of renal function (by estimation of either creatinine clearance or the glomerular filtration rate) in all patients with ACS to permit proper dosing and selection of medications.^{65,75,175}

Elderly patients are more likely than younger ones to have severe CAD that could benefit from invasive management leading to revascularization. However, because elderly patients also often have medical comorbid conditions that increase the risk for adverse outcomes and because patients and physicians exercise more caution regarding invasive procedures, elderly patients have lower rates of invasive procedures. Analyses comparing invasive and conservative management provide support for the use of an early invasive strategy in elderly patients who do not have contraindications to angiography,¹⁷⁶ particularly if the troponin level is elevated at initial evaluation, whereas an early conservative strategy may be preferred in elderly patients without troponin elevation.¹⁴³ Barring comorbid medical conditions that prove to be contraindications, advanced age should not deter otherwise indicated comprehensive treatment of NSTEMI-ACS.

Women (See also Chapter 77)

Women are accounting for an increasingly larger proportion of patients with ACS, now approaching 50%.¹⁷⁷ On average, women with NSTEMI-ACS tend to be a decade older than men, but management of NSTEMI-ACS should be similar regardless of sex.¹⁷⁸ What is considered to be the “typical” manifestation of ACS is based on previous studies that were conducted predominantly in men—such manifestations can differ from the more varied findings in women, in whom the chest discomfort associated with ACS is more commonly atypical. Nonatherosclerotic causes of angina, such as microvascular dysfunction¹⁷⁹ in the coronary circulation without associated epicardial obstructive disease and superimposed thrombosis, are more frequent in women.

Women with ACS are also more likely than men to have abnormal BNP and hsCRP levels,¹⁸⁰ vascular reactivity,¹⁸¹ and functional capacity,¹⁸² probably because of the more complex and varied pathophysiology underlying ACS in women.¹⁸³ Nonetheless, women with elevated circulating troponin or with high-risk noninvasive test results should be referred for coronary angiography, with the understanding that they may be at higher risk for bleeding complications. Because women with ACS are on average older than men, have lower body weight, and are more likely to have impaired renal function, they are

at particular risk for medication overdose of therapies such as LMWH or GP IIb/IIIa inhibitors.¹⁸⁴

Studies investigating the usefulness of intensive DAPT,¹⁸⁵ an early invasive strategy,¹⁴⁷ and the use of high-intensity statins¹⁸⁶ in patients with NSTEMI-ACS have challenged the concept that women fare less well than men with the use of standard intensive therapies. These findings underscore the view that women and men with NSTEMI-ACS as a result of obstructive CAD should receive similar management.

Diabetes Mellitus and Glucose Intolerance (See also Chapter 61)

Diabetes mellitus and glucose intolerance are epidemic in the United States. An estimated 25.6 million (11.3%) U.S. adults (≥ 20 years of age) have diabetes mellitus,¹⁸⁷ and it is undiagnosed in approximately 7 million of them. The annual incidence of new cases of diabetes in 2010 was 1.9 million—double the rate 30 years ago. An estimated additional 35% (79 million) of U.S. adults, as well as half of adults 65 years or older, have prediabetes (based on elevated fasting glucose or hemoglobin A1c levels). Despite advances in management over the past three decades, patients with diabetes mellitus continue to experience a threefold increased risk for age-adjusted cardiovascular mortality when compared with those without diabetes, and almost five of six patients older than 65 years with diabetes die of some form of heart or blood vessel disease.¹⁷⁷ Thus patients with diabetes in whom NSTEMI-ACS develops deserve special consideration.

In GRACE (Global Registry of Acute Coronary Events), more than a fourth of patients with NSTEMI-ACS had diabetes.¹⁸⁸ Even after multivariate adjustment for higher comorbid conditions, diabetes itself confers a 65% increase in the odds for death following NSTEMI-ACS.¹⁸⁹ Even milder forms of impaired glucose metabolism entail increased cardiovascular risk. Metabolic syndrome was present in 25% of patients admitted to the hospital with an ACS in an Israeli national survey, and these patients had a doubling of adjusted mortality.¹⁹⁰

Patients with diabetes should receive established medical therapies for NSTEMI-ACS, as do nondiabetic patients, with additional attention directed toward control of blood glucose and prevention of acute kidney injury. Four key recommendations from an AHA scientific statement on the management of hyperglycemia in patients with ACS¹⁹¹ are that (1) plasma glucose should be measured in all patients with ACS; (2) in patients in an intensive care or coronary care unit, glucose should be monitored closely and intravenous insulin considered in patients with blood glucose levels higher than 180 mg/dL; (3) outside the unit, blood glucose should be maintained at levels lower than 180 mg/dL with subcutaneous insulin; and (4) glucose metabolism should be reassessed after discharge in patients without previous known diabetes mellitus who demonstrated hyperglycemia during hospitalization.

Because patients with diabetes derive similar benefit with an early invasive strategy as nondiabetic patients do, diabetes is included among the characteristics that should prompt adoption of an early invasive strategy.^{69,75} Patients with diabetes have a worse long-term outcome after revascularization than do nondiabetic patients, particularly after PCI,¹⁹² because they have a higher risk for restenosis and progression of disease in nonculprit lesions. Use of GP IIb/IIIa inhibitors appears to have special benefit in diabetic patients who undergo coronary stenting.¹⁹³ In particular, diabetic patients with elevated baseline glucose levels may merit the use of more potent platelet inhibitors such as prasugrel¹⁹¹ (**Fig. 53-14**) because these patients have more severe platelet dysfunction.¹⁹⁴

Chronic Kidney Disease (See also Chapter 88)

The Centers for Disease Control and Prevention estimated that as of 2010, the prevalence of CKD had increased to 14% in U.S. adults older than 20 years.¹⁹⁵ Patients with CKD (including those with even minor reductions in renal function¹⁹⁶) represent a group of special interest because the risk for recurrent ischemic events is higher following ACS,¹⁹⁷ as is treatment-related complications.

Unfortunately, most major cardiovascular clinical trials exclude patients with severe CKD, and thus the evidence base for treatment recommendations in patients with CKD is limited. A meta-analysis of five trials of patients with NSTEMI-ACS and CKD (three of the trials excluded patients with severe renal dysfunction) demonstrated trends toward more favorable outcomes with an early invasive strategy than with conservative management.¹⁴⁴ Thus coronary angiography should be considered in patients with CKD, and the benefits of prompt revascularization should be weighed against the risk for bleeding and contrast-induced nephropathy.

Patients with CKD have a greater risk for bleeding because of impaired platelet function¹⁹⁸ and because of overdosing with anti-thrombotic therapy¹⁹⁹ (Table 53-5; also see Table 88-1). In addition, patients with CKD have increased risk for contrast-induced nephropathy and acute kidney injury. Current guidelines recommend that the risk for contrast-induced nephropathy be assessed by measurement of the ratio of contrast volume to creatinine clearance¹⁷⁵ and that this ratio not exceed 3.7.⁷⁵ Adequate hydration in the periprocedural period is essential,¹⁷⁵ but the evidence that isomolar agents are superior to low-osmolar agents is not compelling.⁷⁵ Physicians should assess renal function in all patients with NSTEMI-ACS.^{6,75} In patients with CKD, the dosage of medications that are cleared renally should be

adjusted; such medications include enoxaparin, bivalirudin, eptifibatide, and tirofiban.

Prinzmetal Variant Angina

In 1959, Prinzmetal and colleagues described a syndrome of ischemic pain that occurred at rest, accompanied by ST-segment elevation.²⁰⁰ Prinzmetal variant angina (PVA) may be associated with acute MI, ventricular tachycardia or fibrillation, and sudden cardiac death. Spasm of a proximal coronary artery with resultant transmural ischemia and abnormalities in left ventricular function are the diagnostic hallmarks of PVA. The precise mechanisms responsible for the spasm have not been established, but a reduction in nitric oxide production by the coronary arterial endothelium or an imbalance between endothelium-derived relaxing and contracting factors may contribute.²⁰¹ The finding of elevated levels of serum hsCRP in many patients supports a contribution of inflammation to the condition.²⁰² Polymorphisms of the α_2 presynaptic and the β_2 postsynaptic receptors may also be associated with PVA.²⁰³

Patients with PVA tend to be younger than those with NSTEMI-ACS attributable to coronary atherosclerosis, and many do not exhibit the classic coronary risk factors except that they are frequently heavy cigarette smokers. The anginal pain is often extremely severe and may be accompanied by syncope related to atrioventricular block, asystole, or ventricular tachyarrhythmia.²⁰⁴ Attacks of PVA tend to cluster between midnight and 8:00 AM.²⁰⁵

Approximately a third of patients with PVA also exhibit severe fixed coronary obstruction and may have a combination of exertion-induced angina with ST-segment depression and episodes of angina at rest with ST-segment elevation. Rarely, PVA appears to be a manifestation of a generalized vasospastic disorder associated with migraine and/or Raynaud phenomenon. PVA can also develop in association with aspirin-induced asthma and administration of 5-fluorouracil and cyclophosphamide. The ergot derivatives used to treat migraine headache and serotonin antagonists (e.g., serotonin reuptake inhibitors used to treat depression) can

FIGURE 53-14 Prasugrel versus clopidogrel in patients with diabetes. Kaplan-Meier curves for prasugrel versus clopidogrel stratified by diabetes status in TRITON-TIMI 38 are shown. The primary efficacy endpoint was a composite of cardiovascular death, nonfatal MI, or nonfatal stroke. DM = diabetes mellitus. (From Wiviott SD, Braunwald E, Angiolillo DJ, et al: Greater clinical benefit of more intensive oral antiplatelet therapy with prasugrel in patients with diabetes mellitus in the trial to assess improvement in therapeutic outcomes by optimizing platelet inhibition with prasugrel—Thrombolysis in Myocardial Infarction 38. *Circulation*;118:1626, 2008.)

TABLE 53-5 Recommendations for the Use of Anticoagulant and Antiplatelet Drugs in Chronic Kidney Disease⁶⁵

DRUG	RECOMMENDATIONS
Enoxaparin	Dose reduction to 1 mg/kg once daily in the case of severe renal failure (CrCl <30 mL/min). Consider monitoring anti-Xa activity.
Fondaparinux	Contraindicated in severe renal failure (CrCl <20 mL/min). Drug of choice in patients with moderately reduced renal function (CrCl 30-60 mL/min).
Bivalirudin	Patients with moderate renal impairment (30-59 mL/min) should receive an infusion of 1.75 mg/kg/hr. If the creatinine clearance is <30 mL/min, reduction of the infusion rate to 1 mg/kg/hr should be considered. No reduction in the bolus dose is needed. If a patient is being maintained on hemodialysis, the infusion rate should be reduced to 0.25 mg/kg/hr.
Abciximab	No specific recommendations for the use of abciximab or for dose adjustment in the case of renal failure. Careful evaluation of risk for hemorrhage is needed before using the drug in patients with renal failure.
Eptifibatide	The infusion dose should be reduced to 1 μ g/kg/min in patients with CrCl <50 mL/min. The bolus dose remains unchanged at 180 μ g/kg/min. Eptifibatide is contraindicated in patients with CrCl <30 mL/min.
Tirofiban	Dose adaptation is required in patients with renal failure; 50% of the bolus dose and infusion is administered if CrCl is <30 mL/min.

Recommendations for the use of drugs listed in this table may vary depending on the exact labeling of each drug in the country where it is used. See also Table 88-1. CrCl = creatinine clearance.

Modified from Hamm CW, Bassand JP, Agewall S, et al: ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation: The Task Force for the Management of Acute Coronary Syndromes (ACS) in Patients Presenting Without Persistent ST-Segment Elevation of the European Society of Cardiology (ESC). *Eur Heart J* 32:2999, 2011.

precipitate episodes of PVA.²⁰⁶ The incidence of PVA has always been greater in Japan than in Western countries, but across the world, the incidence appears to have fallen markedly over the past three decades; this decline may be related in part to the more aggressive use of calcium antagonists for hypertension.²⁰⁷

The key to diagnosis of PVA lies in the detection of episodic ST-segment elevation often accompanied by severe chest pain, usually occurring at rest (**Fig. 53-15A**). Multiple asymptomatic episodes of (silent) ST-segment elevation occur in many patients. ST-segment deviations may be present in any leads, depending on the artery involved. Sometimes serious ventricular arrhythmias²⁰⁸ or transient conduction disturbances²⁰⁹ may occur during periods of ST-segment elevation and result in syncope. Patients with no or mild fixed coronary obstruction tend to experience a more benign course than do patients with PVA and associated severe obstructive lesions.²¹⁰

Provocative Testing

Three provocative tests for coronary spasm can be performed at the time of coronary angiography—hyperventilation (**Fig. 53-15B**), intracoronary acetylcholine, and intracoronary ergonovine—although the third test is no longer available in the United States. These provocative maneuvers should be performed only in patients without obstructive CAD and in whom PVA is suspected, but not yet confirmed. Their use has been declining over the past two to three decades, in part related to the induction of rare but sometimes

fatal arrhythmias. Hyperventilation may also be performed with electrocardiographic monitoring outside the catheterization laboratory, but its sensitivity is low unless the attacks are very frequent (more than five times per week).

Management

Patients with PVA should be strongly urged to discontinue smoking. The mainstay of therapy is a calcium antagonist, alone or usually in combination with a long-acting nitrate. Sublingual or intravenous nitroglycerin often abolishes attacks of PVA promptly, and long-acting nitrates are useful in preventing attacks. The response to beta blockade in patients with PVA is variable.²¹¹ Some patients, particularly those with associated fixed obstructions, exhibit a reduction in the frequency of exertion-induced angina caused primarily by augmentation of myocardial oxygen requirements. In others, however, nonselective beta-blocking agents may actually be detrimental because blockade of β_2 receptors, which mediate coronary dilation, allows unopposed alpha receptor-mediated coronary vasoconstriction to occur.

PCI and occasionally CABG may be helpful in patients with PVA and discrete, proximal fixed obstructive lesions, but revascularization is contraindicated in patients with isolated coronary artery spasm without accompanying fixed obstructive disease. Patients who have experienced ischemia-associated ventricular fibrillation and continue to manifest ischemic episodes despite maximal medical treatment should receive an implantable cardioverter-defibrillator.^{212,213}

Many patients with PVA pass through an acute, active phase, with frequent episodes of angina and cardiac events occurring during the first 6 months after diagnosis. The extent and severity of the underlying CAD and the tempo of the syndrome have a major effect on the incidence of late mortality and MI. Remission occurs more frequently in patients without significant fixed coronary artery stenoses and in those who have discontinued smoking.²¹⁴ For reasons that are not clear, some patients, after a relatively quiescent period of months or even years, experience a recrudescence of vasospastic activity with frequent and severe episodes of ischemia. Fortunately, these patients generally respond to retreatment with calcium antagonists and nitrates. Clinical outcomes are excellent in patients with isolated coronary spasm and no underlying CAD, with no cardiac death or MI occurring in 76 patients monitored for 3 years in the CASPAR (Coronary Artery Spasm in Patients with Acute Coronary Syndrome) study, although about half of the patients frequently experienced angina.²¹⁵

Cardiac Syndrome X

Approximately 15% of patients with NSTEMI-ACS have no obstructive epicardial disease, although they may have electrocardiographic evidence of myocardial ischemia. This condition, commonly referred to as cardiac syndrome X, is described in **Chapter 77**. It must be distinguished from metabolic syndrome X, discussed in **Chapter 42**.

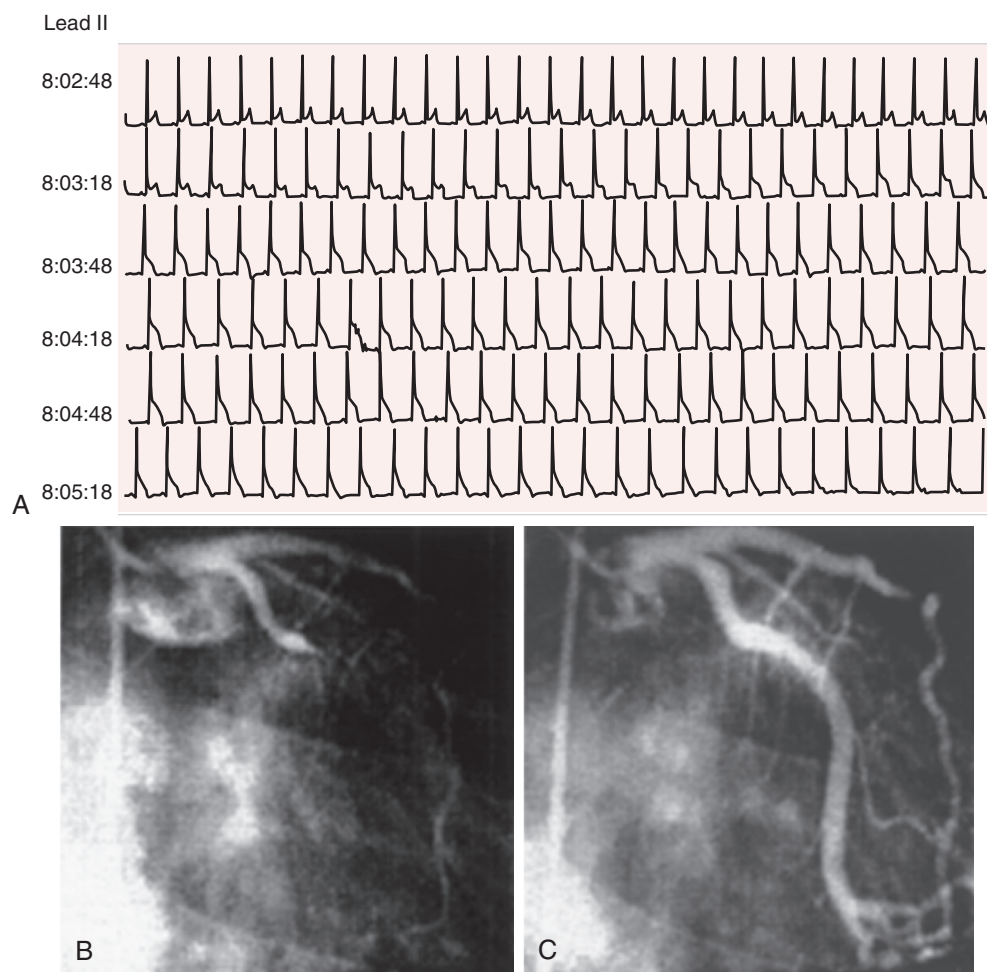

FIGURE 53-15 Observations in a 39-year-old man with Prinzmetal angina. **A**, Continuous electrocardiography during an episode of angina; transient ST-segment elevation (in lead II) was noted on continuous telemetry. **B**, Hyperventilation-induced total occlusion of the proximal left circumflex artery (visible on angiography with the right anterior oblique caudal view). **C**, Spasm that resolved with the administration of intracoronary nitroglycerin and diltiazem. The patient's symptoms were controlled with oral nitrates and calcium channel blockade during a follow-up of 2 years. (From Chen HSV, Pinto DS: Prinzmetal angina. *N Engl J Med* 349:e1, 2003.)

Cocaine and Amphetamines (See also Chapter 68)

Cocaine use causes a marked increase in sympathetic tone by blocking the reuptake of norepinephrine from synapses by preganglionic neurons, thereby resulting in increased myocardial oxygen demand and decreased supply.²¹⁶ This may cause acute myocardial ischemia and be manifested as an ACS. This condition, which has similar findings as amphetamine abuse, occurs more frequently in younger persons and should be especially considered in males younger than 30 years.²¹⁷ The use of psychoactive “street” drugs known as “bath salts” that contain synthetic cathinones with cocaine-like actions may also cause cardiovascular complications, including ACS.²¹⁸

FUTURE PERSPECTIVES

Several aspects of the diagnosis and management of NSTEMI-ACS will continue to advance rapidly and will probably affect numerous aspects of patient care, including the classification, risk assessment, prognostication, and management of patients with NSTEMI-ACS. With future development and more widespread use of more sensitive assays of cTn, it is likely that some myocardial necrosis will be detected in a large majority of patients with NSTEMI-ACS. Hence the frequency of diagnosis of UA will continue to decline and more of these patients will meet the criteria for NSTEMI. Newer biomarkers emerging from proteomic techniques will allow identification of specific causes of NSTEMI-ACS, which in turn will result in more specific and individualized treatment (see Chapter 10). Improvements in noninvasive plaque imaging will lead to the rapid exclusion of ACS when the diagnosis is uncertain and to more rapid and accurate assessment of coronary obstruction and detection of vulnerable plaque.

As new pharmacologic agents that target different aspects of the clotting cascade and platelet function are developed, additional therapeutic options will become available and allow clinicians to select more effective and safer combinations directed toward individual patients' needs. Newer generations of intracoronary stents under development, including totally resorbable stents, may further reduce the risk for restenosis and stent thrombosis—thereby leading to shorter periods of antithrombotic therapy, which will reduce the incidence of bleeding.

Several new therapies are now undergoing phase III trials. These include new, powerful drugs to reduce LDL cholesterol and raise the HDL cholesterol concentration profoundly (see Chapters 42 and 45). Similarly, new interventions are under evaluation for the treatment of resistant hypertension (see Chapter 44). Judicious use of these new treatments will probably further reduce the development of initial and recurrent episodes of NSTEMI-ACS.

Specific populations at highest risk for NSTEMI-ACS have been identified. These groups also paradoxically tend to be undertreated with existing proven therapies. We anticipate that special effort will be made to identify these patients and to intensify both primary and secondary prevention.

As treatment plans become more diverse, more sophisticated electronic information systems will help guide care. To ensure optimal, personalized management of patients with NSTEMI-ACS, appropriate use and analysis of electronic medical records will in turn allow more accurate assessment of outcomes and improve the quality of care.

GUIDELINES

Unstable Angina and Non-ST Elevation Myocardial Infarction

Robert P. Giugliano and Eugene Braunwald

In 2012 the American College of Cardiology Foundation (ACCF) and American Heart Association (AHA) published a focused update on

practice guidelines for the management of patients with unstable angina (UA) and non-ST elevation myocardial infarction (NSTEMI),^{1,2} also referred to as non-ST elevation acute coronary syndrome (NSTEMI-ACS). The 2012 update, which replaced the previous year's focused update³ to the 2007 full guidelines,⁴ reflects the rapid accumulation of new information related to antithrombotic therapy, timing of invasive management, secondary prevention, and treatment of special subgroups (specifically in patients with diabetes and chronic kidney disease [CKD]). This guideline summary highlights the major updates

to the guidelines, with the standard ACCF/AHA classification system being used for indications (classes I to III) and level of evidence (A to C).²

INITIAL EVALUATION AND MANAGEMENT

Patients who experience symptoms suggestive of ACS should not be evaluated by telephone but instead should be referred to a medical facility that permits examination by a physician, assessment of a 12-lead electrocardiogram (ECG), and laboratory testing for cardiac biomarkers of necrosis (*class I; level of evidence: C*). **Figure 53G-1** presents an updated detailed algorithm for the initial evaluation, triage, and management of patients with suspected ACS.

EARLY RISK STRATIFICATION

Class I Recommendations

1. Rapid clinical determination of risk for obstructive coronary artery disease (CAD) (i.e., high, intermediate, or low) should be made in all patients with chest discomfort or other symptoms suggestive of an ACS and considered in patient management. (*Level of evidence: C*.)
2. Patients with chest discomfort or other ischemic symptoms should undergo early risk stratification for cardiovascular events (e.g., death or repeated myocardial infarction [MI]) that focuses on the

history, including anginal symptoms, findings on the physical examination, findings on the ECG, and biomarkers of cardiac injury, and the results should be considered in patient management. (*Level of evidence: C*.)

3. A 12-lead ECG should be obtained and shown to an experienced emergency physician as soon as possible after arrival at the emergency department (ED), with a goal of 10 minutes within ED arrival for all patients with chest discomfort (or anginal equivalent) or other symptoms suggestive of ACS. (*Level of evidence: B₁*.)
4. If the initial ECG is not diagnostic but the patient remains symptomatic and ACS is highly suspected clinically, serial ECGs, initially at 15- to 30-minute intervals, should be obtained to detect the potential for development of ST-segment elevation or depression. (*Level of evidence: B₁*.)
5. Cardiac biomarkers should be measured in all patients with chest discomfort consistent with an ACS. (*Level of evidence: B₁*.)
6. A cardiac-specific troponin is the preferred marker, and if available, it should be measured in all patients with chest discomfort consistent with an ACS. (*Level of evidence: B₁*.)
7. Patients with negative cardiac biomarkers within 6 hours of the onset of symptoms consistent with an ACS should have biomarkers remeasured in the time frame of 8 to 12 hours after symptom onset. (*Level of evidence: B₁*.)
8. The initial evaluation of a patient with a suspected ACS should include consideration of noncoronary causes of the development of unexplained symptoms. (*Level of evidence: C*.)

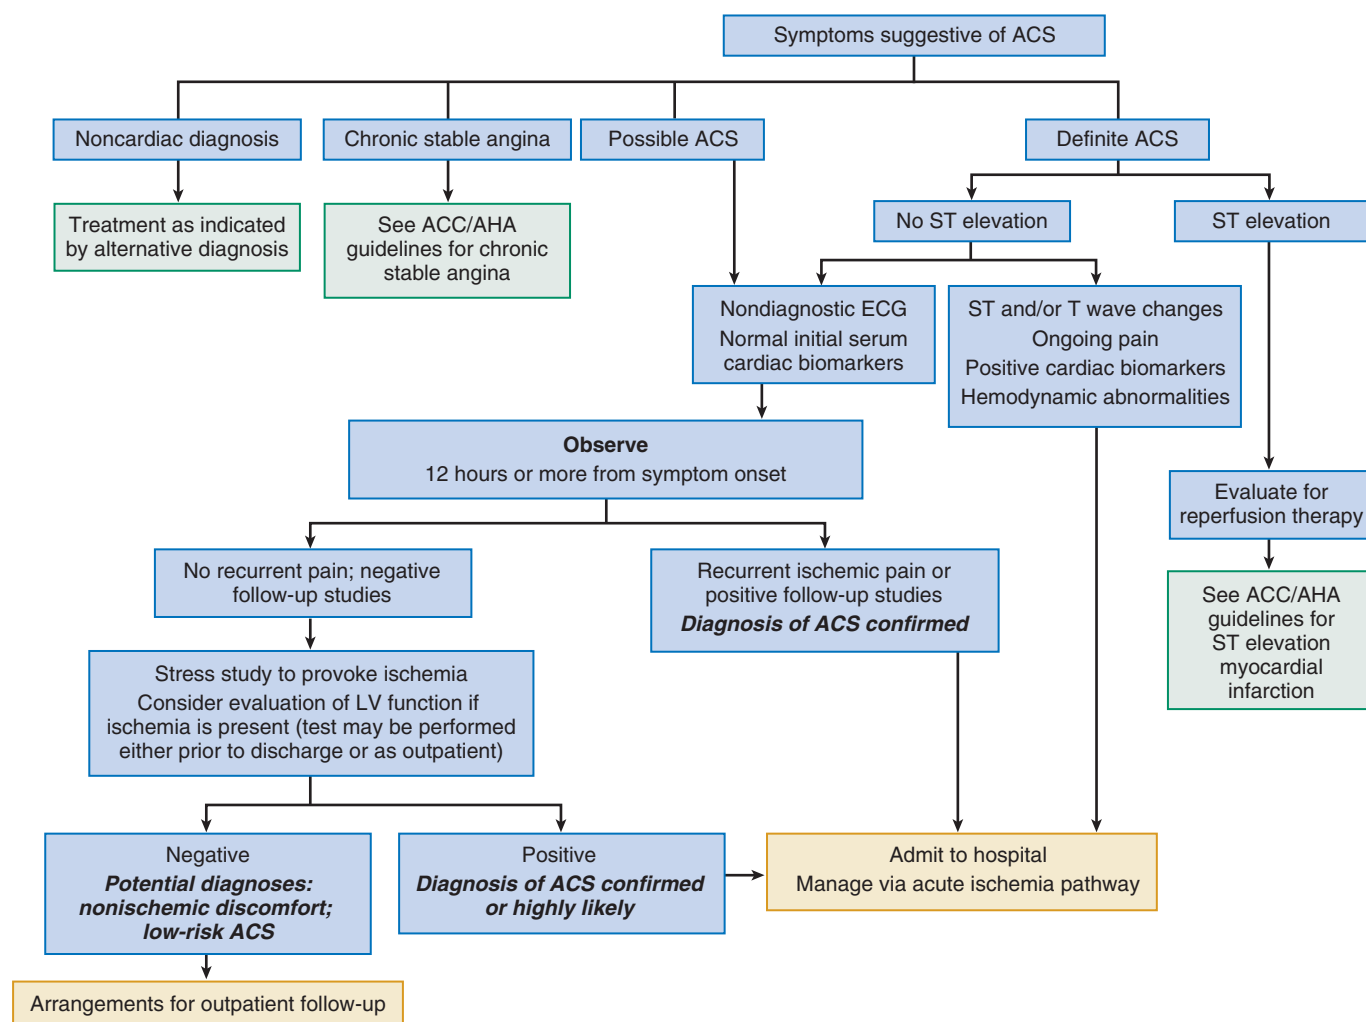

FIGURE 53G-1 Algorithm for the evaluation and management of patients suspected of having an ACS. LV = left ventricular. (From Anderson JL, Adams CD, Antman EM, et al: 2012 ACCF/AHA focused update incorporated into the ACCF/AHA 2007 guidelines for the management of patients with unstable anginal/non-ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e179, 2013.)

Class IIa

1. Use of risk stratification models, such as the TIMI (Thrombolysis In Myocardial Infarction) or GRACE (Global Registry of Acute Coronary Events) risk score or the PURSUIT (Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) risk model, can be useful to assist in decision making with regard to treatment options in patients with a suspected ACS. (*Level of evidence: B.*)
2. It is reasonable to remeasure positive biomarkers at 6- to 8-hour intervals two to three times or until the levels have peaked as an index of infarct size and dynamics of the necrosis. (*Level of evidence: B.*)
3. It is reasonable to obtain supplemental ECG leads V_7 through V_9 in patients whose initial ECG is nondiagnostic to rule out MI secondary to occlusion of the left circumflex artery. (*Level of evidence: B.*)
4. Continuous monitoring of the 12-lead ECG is a reasonable alternative to serial 12-lead recordings in patients whose initial ECG is nondiagnostic. (*Level of evidence: B.*)

Class IIb

1. For patients seen within 6 hours of symptoms suggestive of an ACS, a 2-hour change in the MB fraction of creatine kinase in conjunction with a 2-hour change in troponin may be considered. (*Level of evidence: B.*)
2. Measurement of B-type natriuretic peptide (BNP) or NT-pro-BNP may be considered to supplement assessment of global risk in patients with suspected ACS. (*Level of evidence: B.*)

EARLY HOSPITAL CARE

The class I recommendations for anti-ischemic therapy in the 2012 guideline update are similar to those in previous guidelines and include continuous monitoring of the ECG, supplemental oxygen in selected patients with hypoxemia or respiratory distress, nitrates, beta blockers, and angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Nonsteroidal anti-inflammatory drugs other than aspirin should not be used because they increase risk for mortality, reinfarction, hypertension, heart failure, and myocardial rupture.

Three important changes were made in the recommendations regarding oral antiplatelet therapy in the guideline update, namely, (1) addition of prasugrel as an option in patients managed by percutaneous coronary intervention (PCI), (2) addition of ticagrelor in patients managed medically or with an invasive strategy, and (3) modification of the duration of P2Y₁₂ inhibitor therapy to up to 12 months after an NSTEMI-ACS. In contrast, recommendations regarding anticoagulation therapy did not change substantially in the 2012 update.

INITIAL CONSERVATIVE VERSUS INVASIVE STRATEGIES

Class I

1. An early invasive strategy is indicated in patients with UA/NSTEMI who have refractory angina or hemodynamic or electrical instability (without serious comorbid conditions or contraindications to such procedures). (*Level of evidence: B.*)
2. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in initially stabilized patients with UA/NSTEMI (without serious comorbid conditions or contraindications to such procedures) who have elevated risk for clinical events (*level of evidence: A*). To assess clinical risk, the guidelines endorse the use of a risk stratification model such as the TIMI⁵ or GRACE⁶ risk score or the PRUSUIT risk model.⁷ (*Class IIa, level of evidence: B.*)

Class IIa

1. It is reasonable to choose an early invasive strategy (within 12 to 24 hours of admission) for initially stabilized high-risk patients with UA/NSTEMI. For patients not at high risk, a delayed invasive approach is also reasonable. (*Level of evidence: B.*)

Class IIb

1. In initially stabilized patients, an initially conservative (i.e., a selectively invasive) strategy may be considered as a treatment strategy for patients with UA/NSTEMI (without serious comorbid conditions or contraindications to such procedures) who have elevated risk for clinical events, including those who are troponin positive. (*Level of evidence: B.*)

Class III: No Benefit

1. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with extensive comorbid conditions (e.g., liver or pulmonary failure, cancer) in whom the risks associated with revascularization and comorbid conditions are likely to outweigh the benefits of revascularization. (*Level of evidence: C.*)
2. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with acute chest pain and low likelihood of an ACS. (*Level of evidence: C.*)
3. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) should not be performed in patients who will not consent to revascularization regardless of the findings. (*Level of evidence: C.*)

LATE HOSPITAL CARE, HOSPITAL DISCHARGE, AND POSTHOSPITAL DISCHARGE CARE

Tables 53G-1 and 53G-2 review the recommendations regarding surgical and percutaneous coronary revascularization.

LONG-TERM MEDICAL THERAPY AND SECONDARY PREVENTION

Antiplatelet Therapy

1. For patients with UA/NSTEMI treated medically without stenting, aspirin (or a thienopyridine in patients with aspirin allergy) should be prescribed indefinitely. (*Level of evidence: A.*) Clopidogrel (75 mg/day) or ticagrelor (90 mg twice daily, the aspirin dose should not exceed 100 mg daily) should be prescribed for up to 12 months. (*Level of evidence: B.*)
2. For patients with UA/NSTEMI treated with a stent (bare-metal stent [BMS] or drug-eluting stent [DES]), aspirin should be continued indefinitely (*level of evidence: A*). The duration and maintenance dose of P2Y₁₂ receptor inhibitor therapy should be as follows:
 - a. Clopidogrel, 75 mg daily, prasugrel, 10 mg daily (consider 5 mg in patients weighing <60 kg), or ticagrelor, 90 mg twice daily, should be given for at least 12 months in patients receiving DESs and up to 12 months for those receiving BMSs. (*Level of evidence: B.*)
 - b. If the risk for morbidity because of bleeding outweighs the anticipated benefits afforded by P2Y₁₂ receptor inhibitor therapy, earlier discontinuation should be considered. (*Level of evidence: C.*)
3. Clopidogrel, 75 mg daily (*level of evidence: B*), prasugrel, 10 mg daily (in PCI-treated patients) (*level of evidence: C*), or ticagrelor, 90 mg twice daily (*level of evidence: C*), should be given to patients recovering from UA/NSTEMI when aspirin is contraindicated or not tolerated because of hypersensitivity or gastrointestinal intolerance (despite the use of gastroprotective agents such as proton pump inhibitors).

Class IIa

1. After PCI it is reasonable to use 81 mg/day of aspirin in preference to higher maintenance doses. (*Level of evidence: B.*)

Class IIb

1. For patients with UA/NSTEMI who have an indication for anticoagulation, addition of warfarin may be reasonable to maintain an

TABLE 53G-1 Revascularization to Improve Survival Versus Medical Therapy

ANATOMIC SETTING	COR	LEVEL OF EVIDENCE
Unprotected Left Main Disease or Complex Coronary Artery Disease		
CABG and PCI	I—Heart team approach recommended	C
CABG and PCI	IIa—Calculation of STS and SYNTAX scores	B
Unprotected Left Main Disease*		
CABG	I	B
PCI	IIa—For SIHD when <i>both</i> of the following are present: Anatomic conditions associated with a low risk for PCI procedural complications and a high likelihood of a good long-term outcome (e.g., a low SYNTAX score of <22, ostial or trunk left main CAD) Clinical characteristics that predict significantly increased risk for adverse surgical outcomes (e.g., STS-predicted risk or operative mortality >5%)	B
	IIa—For patients with UA/NSTEMI if not candidates for CABG	B
	IIa—For patients with STEMI when distal coronary flow is TIMI flow grade <3 and PCI can be performed more rapidly and safely than CABG	C
	IIb—For SIHD when <i>both</i> of the following are present: Anatomic conditions associated with a low to intermediate risk for PCI procedural complications and an intermediate to high likelihood of a good long-term outcome (e.g., low to intermediate SYNTAX score of <33, bifurcation left main CAD) Clinical characteristics that predict an increased risk for adverse surgical outcomes (e.g., moderate to severe COPD, disability from previous stroke, previous cardiac surgery; STS-predicted risk for operative mortality >2%)	B
	III: Harm—For SIHD in patients (versus performing CABG) with unfavorable anatomy for PCI and who are good candidates for CABG	B
Three-Vessel Disease with or Without Proximal Left Anterior Descending Artery Disease*		
CABG	I	B
	IIa—It is reasonable to choose CABG over PCI in patients with complex 3-vessel CAD (e.g., SYNTAX score >22) who are good candidates for CABG	B
PCI	IIb—Of uncertain benefit	B
Two-Vessel Disease with Proximal Left Anterior Descending Artery Disease*		
CABG	I	B
PCI	IIb—Of uncertain benefit	B
Two-Vessel Disease Without Proximal Left Anterior Descending Artery Disease*		
CABG	IIa—With extensive ischemia	B
	IIb—Of uncertain benefit without extensive ischemia	C
PCI	IIb—Of uncertain benefit	B
One-Vessel Proximal Left Anterior Descending Artery Disease		
CABG	IIa—With LIMA for long-term benefit	B
PCI	IIb—Of uncertain benefit	B
One-Vessel Disease Without Proximal Left Anterior Descending Artery Disease		
CABG	III: Harm	B
PCI	III: Harm	B
Left Ventricular Dysfunction		
CABG	IIa—EF of 35% to 50%	B
	IIb—EF <35% without significant left main CAD	B
PCI	Insufficient data	
Survivors of Sudden Cardiac Death with Presumed Ischemia-Mediated Ventricular Tachycardia		
CABG	I	B
PCI	I	C
No Anatomic or Physiologic Criteria for Revascularization		
CABG	III: Harm	B
PCI	III: Harm	B

*In patients with multivessel disease who also have diabetes, it is reasonable to choose coronary artery bypass grafting (CABG) (with LIMA) over PCI (class IIa; level of evidence: B).

COPD = chronic obstructive pulmonary disease; COR = class of recommendation; EF = ejection fraction; LIMA = left internal mammary artery; SIHD = stable ischemic heart disease; STS, Society of Thoracic Surgeons; SYNTAX = Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

From Anderson JL, Adams CD, Antman EM, et al: 2012 ACCF/AHA focused update incorporated into the ACCF/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e179, 2013.

TABLE 53G-2 Revascularization to Improve Symptoms with Significant Anatomic (>50% Left Main or >70% Non-Left Main CAD) or Physiologic (FFR <0.80) Coronary Artery Stenoses

CLINICAL SETTING	COR	LEVEL OF EVIDENCE
>1 significant stenosis amenable to revascularization and unacceptable angina despite GDMT	I—PCI I—CABG	A
>1 significant stenosis and unacceptable angina in whom GDMT cannot be implemented because of contraindications to medications, adverse effects, or patient preferences	Ila—CABG Ila—PCI	C
Previous CABG with >1 significant stenosis associated with ischemia and unacceptable angina despite GDMT	Ila—PCI Iib—CABG	C
Complex 3-vessel CAD (e.g., SYNTAX score >22) with or without involvement of the proximal LAD artery and a good candidate for CABG	Ila—CABG preferred over PCI	B
Viable ischemic myocardium perfused by coronary arteries not amenable to grafting	Iib—TMR as an adjunct to CABG	B
No anatomic or physiologic criteria for revascularization	III: Harm—CABG III: Harm—PCI	C

CABG = coronary artery bypass grafting; COR = class of recommendation; FFR = fractional flow reserve; GDMT = guideline-directed medical therapy; SYNTAX = Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery; TMR = transmyocardial laser revascularization.

From Anderson JL, Adams CD, Antman EM, et al: 2012 ACCF/AHA focused update incorporated into the ACCF/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e179, 2013.

international normalized ratio [INR] of 2.0 to 3.0. (*Level of evidence: B.*) A target INR of 2.0 to 2.5 is preferable while giving dual antiplatelet therapy, especially in older patients and those at increased risk for bleeding.

Warfarin

Class I

1. Use of warfarin in conjunction with aspirin and/or P2Y₁₂ receptor inhibitor therapy is associated with an increased risk for bleeding, and patients and clinicians should watch for bleeding, especially gastrointestinal bleeding, and seek medical evaluation for evidence of bleeding. (*Level of evidence: A.*)

SPECIAL GROUPS

Diabetes Mellitus

Class I

1. Medical treatment in the acute phase of UA/NSTEMI and decisions on whether to perform stress testing, angiography, and revascularization should be similar in patients with and without diabetes mellitus. (*Level of evidence: A.*)

Class IIa

1. For patients with UA/NSTEMI and multivessel disease, coronary artery bypass grafting (CABG) with use of the internal mammary arteries can be more beneficial than PCI in patients being treated for diabetes mellitus. (*Level of evidence: B.*)
2. PCI is reasonable for UA/NSTEMI patients with diabetes mellitus, single-vessel disease, and inducible ischemia. (*Level of evidence: B.*)

Chronic Kidney Disease

Class I

1. Creatinine clearance should be estimated in patients with UA/NSTEMI, and doses of renally cleared medications should be adjusted according to the pharmacokinetic data for specific medications. (*Level of evidence: B.*)

2. Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration. (*Level of evidence: B.*)
3. Calculation of the contrast volume-to-creatinine clearance ratio is useful to predict the maximum volume of contrast media that can be given without significantly increasing the risk for contrast-induced nephropathy. (*Level of evidence: B.*)

Class IIa

1. An invasive strategy is reasonable for patients with mild (stage 2) and moderate (stage 3) CKD. (*Level of evidence: B.*) (There are insufficient data on the benefit or risk associated with an invasive strategy in patients with UA/NSTEMI and advanced CKD [stages 4 and 5].)

GUIDELINES, 1231

Stable ischemic heart disease (SIHD) is most commonly caused by atheromatous plaque that obstructs or gradually narrows one or more of the epicardial coronary arteries. The pathogenesis of atherosclerosis is described in [Chapter 41](#). However, other contributors, such as endothelial dysfunction, microvascular disease, and vasospasm, may also exist alone or in combination with coronary atherosclerosis and may be the dominant cause of myocardial ischemia in some patients ([Fig. 54-1](#)).^{1,2} Thus the concept that ischemic heart disease (IHD) is synonymous with obstructive coronary atherosclerosis represents an overly simplified view.^{1,2}

Factors that predispose to coronary atherosclerosis are discussed in [Chapter 42](#), control of coronary blood flow in [Chapter 49](#), ST-segment elevation myocardial infarction (MI) in [Chapters 51 and 52](#), non-ST-segment elevation acute coronary syndromes (ACSs) in [Chapter 53](#), and sudden cardiac death, another significant consequence of coronary artery disease (CAD), in [Chapter 39](#).

The clinical findings in patients with IHD are highly variable. Chest discomfort is usually the predominant symptom in chronic (stable) angina, unstable angina, Prinzmetal (variant) angina, microvascular angina, and acute MI. However, manifestations of IHD also occur in which chest discomfort is absent or not prominent, such as asymptomatic (silent) myocardial ischemia, heart failure, cardiac arrhythmias, and sudden death. Notably, there may be features of atypical angina or anginal equivalents that characterize IHD, such as midepigastriac discomfort, effort intolerance, dyspnea, and excessive fatigue, which are observed more frequently in women, older adults, and individuals with diabetes. Obstructive CAD also has nonatherosclerotic causes, including congenital abnormalities of the coronary vessels, myocardial bridging, coronary arteritis in association with the systemic vasculitides, and radiation-induced CAD. Myocardial ischemia and angina pectoris may also occur in the setting of extreme myocardial O₂ demand with or without underlying obstructive CAD, as in the case of aortic valve disease ([see Chapter 63](#)), hypertrophic cardiomyopathy ([see Chapter 66](#)), and idiopathic dilated cardiomyopathy ([see Chapter 65](#)).

MAGNITUDE OF THE PROBLEM

The importance of IHD in contemporary society is attested to by the almost epidemic number of persons afflicted ([see Chapter 1](#)). It is estimated that 15,400,000 Americans have IHD, 7,800,000 of whom have angina pectoris and 7,600,000 have had MI.³ Based on data from the Framingham Heart Study, the lifetime risk for the development of symptomatic CAD after 40 years of age is 49% for men and 32% for women. In 2010, IHD accounted for 48% of all deaths caused by cardiovascular disease and was the single most frequent cause of death

in American men and women; it resulted in more than one in six deaths in the United States.³ The economic cost of IHD is formidable, and in the United States in 2010 it was estimated to be \$204.4 billion.³ Despite a steady decline in age-specific mortality from CAD over the past several decades, IHD is now the leading cause of death worldwide, and it is expected that the rate of CAD will only accelerate in the coming decades with the burden shifting progressively to lower socioeconomic groups; contributory factors include aging of the population, increases in the worldwide prevalence of obesity and type 2 diabetes, and a rise in cardiovascular risk factors in younger generations. The World Health Organization has estimated that by 2020, the global number of deaths from CAD will have risen from 7.6 million in 2005 to 11.1 million ([see Chapter 1](#)).⁴

STABLE ANGINA PECTORIS

Clinical Manifestations

Characteristics of Angina ([See Chapter 11](#))

Angina pectoris is a discomfort in the chest or adjacent areas caused by myocardial ischemia. It is usually precipitated by exertion and is associated with a disturbance in myocardial function. Acute MI, which is generally associated with prolonged, severe pain occurring at rest ([see Chapter 51](#)), and unstable angina, which is characterized by an accelerated pattern of increasing frequency and tempo of angina or angina at rest ([see Chapter 53](#)), are discussed separately. Heberden's initial description of angina as conveying a sense of "strangling and anxiety" is still remarkably pertinent. Other adjectives frequently used to describe this distress include constricting, suffocating, crushing, heavy, and squeezing. In other patients, the quality of the sensation is more vague and described as a mild pressure-like discomfort, tightness, an uncomfortable numbness, or a burning sensation. The site of the discomfort is usually retrosternal, but radiation is common and generally occurs down the ulnar surface of the left arm; the right arm and the outer surfaces of both arms may also be involved ([Fig. e54-1](#)). Epigastric discomfort alone or in association with chest pressure may occur and can masquerade as indigestion. Anginal discomfort above the mandible or below the epigastrium is rare. Anginal equivalents (i.e., symptoms of myocardial ischemia other than angina), such as dyspnea, faintness, fatigue, and eructations, are common, particularly in women and older adults. A history of abnormal exertional dyspnea may be an indicator of IHD even when angina is absent or no evidence of CAD can be found on the electrocardiogram (ECG). Nocturnal angina may be a manifestation of unstable angina but should also raise suspicion of sleep apnea ([see Chapter 75](#)). Postprandial angina, presumably caused by redistribution of coronary blood flow, may be a marker of severe CAD.

FIGURE e54-1 Location of discomfort and cause of chest symptoms. The location of angina is usually retrosternal, but radiation is common. An epigastric location of angina may also occur. (Modified from Braunwald E: *The history*. In Zipes D, Libby P, Bonow RO, Braunwald E [eds]: *Braunwald's Heart Disease*. 7th ed. Philadelphia, WB Saunders, 2005.)

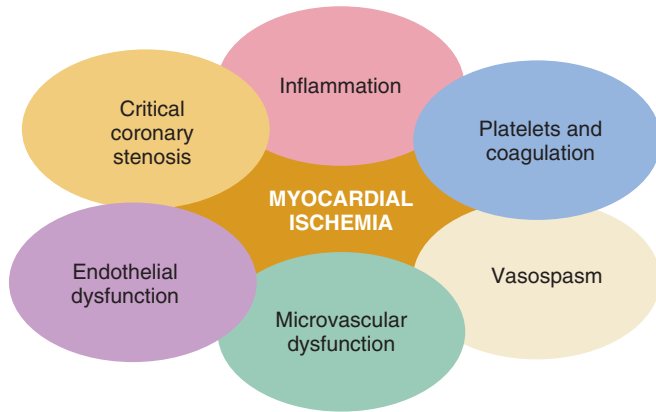

FIGURE 54-1 Pathophysiology of ischemic heart disease. The notion that ischemic heart disease is synonymous with critical stenoses of epicardial coronary arteries is overly simplified. The potential contributors to ischemic heart disease are multiple. (Modified from Marzilli M, Bairey Merz CN, Boden WE, et al: Obstructive coronary atherosclerosis and ischemic heart disease: An elusive link. *J Am Coll Cardiol* 60:951, 2012.)

The typical episode of angina pectoris usually begins gradually and reaches its maximum intensity over a period of minutes before dissipating. It is unusual for angina pectoris to reach its maximum severity within seconds, and it is characteristic that patients with angina generally prefer to rest, sit, or stop walking during episodes. Chest discomfort while walking in the cold or uphill is suggestive of angina. Features suggesting the absence of angina pectoris include pleuritic pain, chest pain localized with the tip of one finger, pain reproduced by movement or palpation of the chest wall or arms, and constant pain lasting many hours or, alternatively, very brief episodes of pain lasting seconds. Pain radiating into the lower extremities is also a highly unusual manifestation of angina pectoris.

Typical angina pectoris is relieved within minutes by rest or the use of short-acting nitroglycerin. Response to the latter is often a useful diagnostic tool, although it should be remembered that esophageal pain and other syndromes may also respond to nitroglycerin. A delay of more than 5 to 10 minutes before relief is obtained with rest and nitroglycerin suggests that the symptoms are either not caused by ischemia or are caused by severe ischemia, as with acute MI or unstable angina. The phenomenon of first-effort or warm-up angina is used to describe the ability of some patients in whom angina develops with exertion to continue subsequently at the same or even greater level of exertion without symptoms after an intervening period of rest. This attenuation of myocardial ischemia observed with repeated exertion has been postulated to be caused by ischemic preconditioning (see Chapter 49) and appears to require preceding ischemia of at least moderate intensity to induce the warm-up angina phenomenon.

Grading of Angina Pectoris

A system of grading the severity of angina pectoris proposed by the Canadian Cardiovascular Society (CCS) has gained widespread acceptance (see Table 11-1).⁵ The system is a modification of the New York Heart Association (NYHA) functional classification but allows patients to be categorized in more specific terms. Other grading systems include a specific activity scale developed by Goldman and associates and an anginal score developed by Califf and colleagues.⁶ The Goldman scale is based on the metabolic cost of specific activities and appears to be valid when used by both physicians and nonphysicians. The anginal score of Califf and coworkers integrates the clinical features and tempo of angina together with ST and T wave changes on the ECG and offers independent prognostic information beyond that provided by age, sex, left ventricular (LV) function, and coronary angiographic anatomy. A limitation of all these grading systems is their dependence on accurate patient observation and patients' widely varying tolerance of symptoms. Functional estimates

based on the CCS criteria have shown a reproducibility of only 73% and do not correlate well with objective measures of exercise performance.

Mechanisms. The mechanisms of cardiac pain and the neural pathways involved are poorly understood. It is presumed that angina pectoris results from ischemic episodes that excite chemosensitive and mechanosensitive receptors in the heart.⁷ Stimulation of these receptors results in the release of adenosine, bradykinin, and other substances that excite the sensory ends of sympathetic and vagal afferent fibers.⁸ The afferent fibers traverse the nerves that connect to the upper five thoracic sympathetic ganglia and the upper five distal thoracic roots of the spinal cord. Impulses are transmitted by the spinal cord to the thalamus and hence to the neocortex. Data from animal studies have identified the vanilloid receptor-1 (VR1), an important sensor for somatic nociception, to be present on sensory nerve endings in the heart and have suggested that VR1 functions as a transducer of myocardial tissue ischemia and may play a role in ischemic preconditioning.

Within the spinal cord, cardiac sympathetic afferent impulses may converge with impulses from somatic thoracic structures, which may be the basis for referred cardiac pain—for example, to the chest. In comparison, cardiac vagal afferent fibers synapse in the nucleus tractus solitarius of the medulla and then descend to excite the upper cervical spinothalamic tract cells, which may contribute to the anginal pain experienced in the neck and jaw. Moreover, vagal input in the nucleus tractus solitarius may lead to stimulation of efferent impulses in the autonomic system that contribute to nausea and emesis.⁹ Positron emission tomography (PET) of the brain in subjects with silent ischemia has suggested that failed transmission of signals from the thalamus to the frontal cortex may contribute to this phenomenon, along with impaired afferent signaling, such as that caused by autonomic neuropathy. Silent ischemia in diabetic patients, for example, has been proposed to be related to failed development of the cardiac sensory system because of reduced nerve growth factor.⁹

Differential Diagnosis of Chest Pain

Esophageal Disorders

Common disorders that may simulate or coexist with angina pectoris are gastroesophageal reflux and disorders of esophageal motility, including diffuse spasm and nutcracker esophagus. To compound the difficulty in distinguishing between angina and esophageal pain, both may be relieved by nitroglycerin. However, esophageal pain is often relieved by milk, antacids, foods, or occasionally, warm liquids.

Esophageal Motility Disorders

Esophageal motility disorders are not uncommon in patients with retrosternal chest pain of unclear cause and should be specifically excluded or confirmed, if possible. In addition to chest pain, most such patients have dysphagia. Both IHD and esophageal disease are common clinical entities that may coexist. Diagnostic evaluation for an esophageal disorder may be indicated in patients with IHD who have a poor symptomatic response to antianginal therapy in the absence of documented severe ischemia.

Biliary Colic

Although visceral symptoms are commonly associated with myocardial ischemia (particularly acute inferior MI; see Chapter 51), cholecystitis and related hepatobiliary disorders may also mimic ischemia and should always be considered in patients with atypical chest discomfort, particularly those with diabetes. The pain is steady, usually lasts 2 to 4 hours, and subsides spontaneously, without any symptoms between attacks. It is generally most intense in the right upper abdominal area but may also be felt in the epigastrium or precordium. This discomfort is often referred to the scapula, may radiate around the costal margin to the back, or may in rare cases be felt in the shoulder and suggest diaphragmatic irritation.

Costochondritis

In 1921 Tietze first described a syndrome of local pain and tenderness, generally limited to the anterior chest wall and associated with swelling of costal cartilage. The full-blown Tietze syndrome (i.e., pain

Other Musculoskeletal Disorders

Other Causes of Angina-Like Pain

Pulmonary embolism is initially characterized by dyspnea as the cardinal symptom, but chest pain may also be present ([see Chapter 73](#)). Pleuritic pain suggests pulmonary infarction, and a history of exacerbation of the pain with inspiration, along with a pleural friction rub, if present, helps distinguish it from angina pectoris.

The pain of acute pericarditis (see **Chapter 71**) may at times be difficult to distinguish from angina pectoris. However, pericarditis tends to occur in younger patients, and the diagnosis depends on the combination of chest pain not relieved by rest or nitroglycerin, exacerbation by movement or deep inspiration, and lying flat; a

The classic symptom of aortic dissection is a severe, often sharp pain that radiates to the back (**see Chapter 57**).

Many patients with SIHD have normal findings on physical examination, and thus the single best clue to the diagnosis of angina is the clinical history. Nonetheless, careful examination may reveal the presence or evidence of risk factors for coronary atherosclerosis or the consequences of myocardial ischemia ([see Chapter 11](#)).

Angina pectoris results from myocardial ischemia, which is caused by an imbalance between myocardial O_2 requirements and myocardial O_2 supply. The former may be elevated by increases in heart rate, LV wall stress, and contractility ([see Chapter 49](#)); the latter is determined by coronary blood flow and coronary arterial O_2 content ([Fig. 54-2](#)). The clinical precipitants and manifestations of supply-demand imbalance are discussed in this section. The pathobiology of atherosclerosis is discussed in [Chapter 41](#). See [Chest Pain with a Normal Coronary Arteriogram](#) in this chapter and [Chapter 49](#) for discussion of other abnormalities in coronary function and contributors to myocardial ischemia in the absence of critical coronary obstruction.

In this condition, sometimes termed *demand angina*, the myocardial O₂ requirement increases in the presence of a constant and usually restricted O₂ supply. The increased requirement commonly stems from release of norepinephrine by adrenergic nerve endings in the heart and vascular bed, a physiologic response to exertion, emotion, or mental stress. Of great importance to the myocardial O₂ requirement is the rate at which any task is carried out. Hurrying is particularly likely to precipitate angina, as are efforts involving motion of the hands over the head. Mental and emotional stress may also precipitate angina, presumably by increased hemodynamic and catecholamine responses to stress, increased adrenergic tone, and reduced vagal activity. The combination of physical exertion and emotion in association with sexual activity may precipitate angina pectoris.

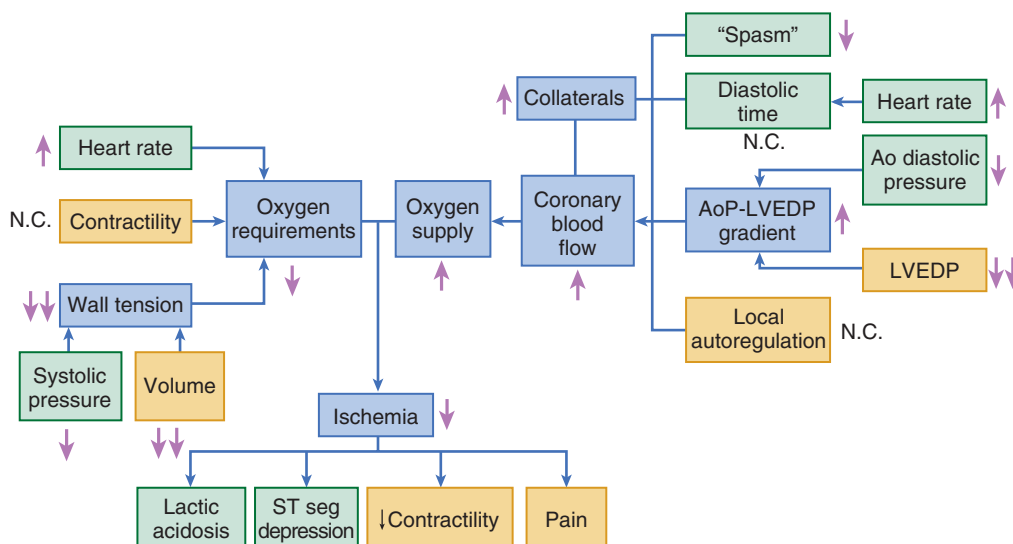

FIGURE 54-2 Factors influencing the balance between myocardial O₂ requirement (*left*) and supply (*right*). Arrows indicate effects of nitrates. In relieving angina pectoris, nitrates exert favorable effects by reducing O₂ requirements and increasing supply. Although a reflex increase in heart rate would tend to reduce the time for coronary flow, dilation of collaterals and enhancement of the pressure gradient for flow to occur as left ventricular end-diastolic pressure (LVEDP) falls tend to increase coronary flow. AoP-LVEDP = aortic pressure minus LVEDP; N.C. = no change. (From Frishman WH: *Pharmacology of the nitrates in angina pectoris*. *Am J Cardiol* 56:81, 1985.)

Anger may produce constriction of coronary arteries with preexisting narrowing, without necessarily affecting O₂ demand. Other precipitants of angina include physical exertion after a heavy meal and the excessive metabolic demands imposed by chills, fever, thyrotoxicosis, tachycardia from any cause, exposure to the cold, and hypoglycemia.

Angina Caused by Transiently Decreased O₂ Supply

Evidence has suggested that not only unstable angina but also chronic stable angina may be caused by transient reductions in O₂ supply, a condition sometimes termed *supply angina*, as a consequence of coronary vasoconstriction that results in dynamic stenosis. In the presence of organic stenoses, platelet thrombi and leukocytes may elaborate vasoconstrictor substances such as serotonin and thromboxane A₂. In addition, endothelial damage in atherosclerotic coronary arteries decreases production of vasodilator substances, which may result in an abnormal vasoconstrictor response to exercise and other stimuli. A variable threshold of myocardial ischemia in patients with chronic stable angina may be caused by dynamic changes in peristhenotic smooth muscle tone and also by constriction of arteries distal to the stenosis. Patients with resulting “variable-threshold angina” may have good days, when they are capable of substantial physical activity, as well as bad days, when even minimal activity can cause clinical and/or electrocardiographic evidence of myocardial ischemia or angina at rest. They often complain of a circadian variation in angina that is more common in the morning. Angina on exertion and sometimes even at rest may be precipitated by cold temperature, emotion, and mental stress.

In rare instances, severe dynamic obstruction may develop alone in patients without organic obstructing lesions and can cause myocardial ischemia and angina at rest (see [Prinzmetal \[Variant\] Angina](#); see also [Chapters 49 and 53](#)). On the other hand, in patients with severe fixed obstruction in one or more epicardial coronary arteries, only a minor increase in dynamic obstruction is necessary for coronary blood flow to fall below a critical level and cause myocardial ischemia.

Importance of Pathophysiologic Considerations in Configuring Therapy

The pathophysiologic and clinical correlations of ischemia in patients with SIHD may have important implications for the selection of anti-ischemic agents, as well as for their timing. The greater the contribution from increased myocardial O₂ demand associated with tachycardia or increased contractility, the greater the likelihood that beta-blocking agents will be effective; nitrates and calcium channel-blocking agents, at least hypothetically, are more likely to be effective in episodes caused primarily by coronary vasoconstriction. The finding that an increase in myocardial O₂ requirement precedes episodes of ischemia in most patients with chronic stable angina—that is, that they have demand angina—argues in favor of controlling the heart rate and blood pressure as a primary therapeutic approach.

EVALUATION AND MANAGEMENT

Noninvasive Testing

Biochemical Tests

In patients with SIHD, metabolic abnormalities that are risk factors for the development of CAD are frequently detected. Such abnormalities include hypercholesterolemia and other dyslipidemias (see [Chapter 45](#)), carbohydrate intolerance, and insulin resistance. Moreover, chronic kidney disease is strongly associated with risk for atherosclerotic vascular disease (see [Chapter 88](#)). All patients with established or suspected CAD warrant biochemical evaluation of total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglyceride, serum creatinine (estimated glomerular filtration rate [eGFR]), and fasting blood glucose levels.

Other biochemical markers have also been shown to be associated with higher risk for future cardiovascular events (see [Chapter 42](#)). Measurement of lipoprotein(a) and other lipid elements that are particularly atherogenic, such as apolipoprotein B and small dense LDL, appears to add prognostic information to the measurement of total cholesterol and LDL and may be considered a secondary target for therapy in patients who have achieved therapeutic targets for LDL.¹⁰ However, no consensus has been reached regarding routine measurement, and a simple approach based on calculation of non-HDL cholesterol (particularly in patients with triglyceride levels >200 mg/dL) may capture important information related to the presence of residual very low-density lipoprotein (VLDL) atherogenic remnants.¹¹ Similarly, lipoprotein-associated phospholipase A₂ (Lp-PLA₂) is associated with risk for coronary heart disease (CHD), as well as for recurrent events, independent of traditional risk factors.¹² An assay for Lp-PLA₂ is available for clinical use but has not been incorporated into guidelines for routine risk assessment.¹³ Inhibitors of Lp-PLA₂ are under investigation for the treatment of IHD.^{14,15} Although homocysteine has also been linked to atherogenesis and correlates with risk for CAD, prospective studies, in aggregate, have supported, at most, a modest increase in risk associated with elevated homocysteine levels and have not consistently demonstrated a relationship independent of traditional risk factors or other biochemical markers.¹⁶ Moreover, placebo-controlled trials have failed to demonstrate clinical benefit associated with folate replacement therapy as an intervention to mitigate the adverse effects of increased homocysteine levels.¹⁷ Therefore general screening for elevated homocysteine levels is not recommended.

Advances in understanding regarding the pathobiology of atherothrombosis (see [Chapter 41](#)) have generated interest in inflammatory biomarkers as noninvasive indicators of underlying atherosclerosis and cardiovascular risk. Measurement of the acute-phase protein high-sensitivity C-reactive protein (hsCRP) has shown a consistent relationship to risk for incident cardiovascular events, as well as with imaging findings of vulnerable atherosclerosis.¹⁸ The prognostic value of hsCRP is additive to traditional risk factors, including lipids¹⁹; however, its incremental clinical value for screening continues to be debated.²⁰ Measurement of hsCRP in patients judged to be at intermediate risk by global risk assessment (10-year risk for CHD of 10% to 20%) may help direct further evaluation and therapy for primary prevention of CHD (see [Chapter 42](#)) and may be useful as an independent marker of prognosis in patients with established CAD.¹⁹ In a randomized, double-blind trial involving patients free of known atherosclerosis with an LDL level less than 130 mg/dL who were identified to be at higher vascular risk by virtue of elevated hsCRP (>2 mg/L), treatment with a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (statin) versus placebo significantly reduced the risk for cardiovascular death and incident atherosclerotic vascular events.²¹ On the basis of this finding, some professional society guidelines recommend the use of hsCRP as a risk indicator to support statin therapy for primary prevention in individuals at moderate global risk.²² Other biomarkers of inflammation, such as interleukin-6, myeloperoxidase, growth factors, and metalloproteinases, remain under study as potential markers of underlying atherosclerosis.⁶ Genetic testing, including multigene expression from peripheral blood cells,²³ is also under investigation. For example, a peripheral blood gene expression score based on expression values for 23 genes from peripheral blood cells has been developed and validated to assess the risk for obstructive CAD; a high negative predictive value with a very low rate of major adverse cardiac events over a 1-year period was demonstrated in patients with a low gene expression score.²³

Biomarkers of Myocyte Injury, Ischemia, and Hemodynamic Stress

Blood levels of cardiac markers of myocardial necrosis are typically used to differentiate patients with acute MI from those with SIHD. However, with more sensitive assays for cardiac troponin, circulating biomarkers of myocyte injury have now been detected in patients with SIHD and shown to have a graded relationship with the

FIGURE 54-3 Incidence of cardiovascular death according to the concentration of high-sensitivity troponin T (hs-TnT) (**A**) and N-terminal pro-B-type natriuretic peptide (NT-proBNP) (**B**) in patients with stable CAD subgrouped by quartiles of biomarker concentration. **A**, Circulating cardiac troponin was detected in 97.7% of individuals via a sensitive assay, with 11.1% having a concentration that exceeded the 99th percentile reference limit. During a median follow-up of 5.2 years, the incidence of cardiovascular death was associated with the baseline concentration of hs-TnT. This relationship was apparent at concentrations of hs-TnT below the 99th percentile reference limit (0.013 $\mu\text{g/L}$). **B**, The NT-proBNP concentration was also strongly associated with risk for cardiovascular mortality; prognostic accuracy improved when NTproBNP was considered alongside traditional clinical risk indicators. (**A**, From Omland T, de Lemos JA, Sabatine MS, et al: A sensitive cardiac troponin T assay in stable coronary artery disease. *N Engl J Med* 361:2538, 2009; **B**, from Omland T, Sabatine MS, Jablonski KA, et al: Prognostic value of B-type natriuretic peptides in patients with stable coronary artery disease. *J Am Coll Cardiol* 50:201, 2007.)

subsequent risk for cardiovascular mortality and heart failure (Fig. 54-3A).²⁴ Although such evidence may lead to new applications of troponin in patients with SIHD, clinical use in this population is currently not recommended.²⁵ Biomarkers of myocardial ischemia are also under study. For example, the plasma concentration of brain natriuretic peptide (BNP) increases in response to spontaneous or provoked ischemia. Although BNP and N-terminal pro-BNP may not have sufficient specificity to aid in the diagnosis of SIHD, their concentration is associated with risk for cardiovascular events in those at risk for and with established CAD (Fig. 54-3B).²⁶ Other novel biomarkers of hemodynamic stress, such as midregional pro-adrenomedullin (MR-proADM) and midregional pro-atrial natriuretic peptide (MR-proANP), also appear to provide incremental information regarding the risk for cardiovascular death in patients with SIHD and may be useful for guiding decisions regarding therapy.²⁷ Growth differentiation factor-15,²⁸ ST2, and galectin-3²⁹ are other biomarkers that may putatively reflect myocardial ischemia or its consequence and have been associated with outcomes in clinical studies of patients with SIHD.

Resting Electrocardiogram

Findings on the resting ECG (see Chapter 12) are normal in approximately half of patients with SIHD, and even patients with severe CAD may have a normal tracing at rest. A normal resting ECG suggests the presence of normal resting LV function and is an unusual finding in a patient with an extensive previous MI. The most common abnormalities on the ECG in patients with chronic CAD are nonspecific ST-T wave changes with or without abnormal Q waves. In patients with known CAD, however, the occurrence of ST-T wave abnormalities on the resting ECG (particularly if obtained during an episode of angina) can correlate with the severity of the underlying heart disease. This correlation explains the adverse association of ST-T wave changes with prognosis in these patients. In contrast, a normal resting ECG is a more favorable long-term prognostic sign in patients with suspected or definite CAD.

Interval ECGs may reveal the development of Q wave MIs that have gone unrecognized clinically. Various conduction disturbances, most frequently left bundle branch block and left anterior fascicular block, may occur in patients with SIHD. They are often associated with impairment of LV function, reflect multivessel CAD, and are an indicator of a relatively poor prognosis. Various arrhythmias, especially ventricular premature beats, may be present on the ECG, but they too have low sensitivity and specificity for accurately detecting CAD. LV hypertrophy on the ECG implies suggests a poor prognosis in patients with chronic stable angina. This finding implies the presence of

underlying hypertension, aortic stenosis, hypertrophic cardiomyopathy, or previous MI with remodeling and warrants further evaluation, such as echocardiography to assess LV size, wall thickness, and function.

During an episode of angina pectoris, findings on the ECG become abnormal in 50% or more of patients with normal resting ECGs. The most common finding is ST-segment depression, although ST-segment elevation and normalization of previous resting ST-T wave depression or inversion (pseudonormalization) may develop. Ambulatory ECG monitoring (see [Silent Myocardial Ischemia](#)) provides a quantitative estimate of the frequency and duration of ischemic episodes during routine activities; however, its sensitivity for detecting CAD is less than that of exercise electrocardiography.

Noninvasive Stress Testing (See Chapters 13, 14, and 16).

Noninvasive stress testing can provide useful and often indispensable information to establish the diagnosis and estimate the prognosis in patients with chronic stable angina.⁶ However, indiscriminate use of such tests yields limited incremental information beyond that provided by the physician's detailed and thoughtful clinical assessment. Appropriate application of noninvasive tests requires consideration of Bayesian principles, which state that the reliability and predictive accuracy of any test are defined not only by its sensitivity and specificity but also by the prevalence of disease (or pretest probability) in the population under study. A reasonable estimate of the pretest probability of CAD may be made on clinical grounds (Table 54-1).

Noninvasive testing should be performed only if the incremental information provided by a test is likely to alter the planned management strategy. The value of noninvasive stress testing is greatest when the pretest likelihood is intermediate because the test result is likely to have the greatest effect on the post-test probability of CAD and hence on clinical decision making.

Exercise Electrocardiography (See Chapter 13)

Diagnosis of Coronary Artery Disease. The exercise ECG is particularly helpful in patients with chest pain syndromes who are considered to have a moderate probability of CAD and in whom the resting ECG is normal, provided that they are capable of achieving an adequate workload.³⁰ Although the incremental diagnostic value of exercise testing is limited in patients in whom the estimated prevalence of CAD is high or low, the test provides useful additional information about the degree of functional limitation in both groups of patients and about the severity of ischemia and prognosis in patients with a high pretest probability of CAD. Interpretation of the exercise test should include consideration of the patient's exercise capacity (duration and metabolic equivalents) and clinical, hemodynamic, and electrocardiographic responses.

Influence of Antianginal Therapy. Antianginal pharmacologic therapy may reduce the sensitivity of exercise testing as a screening

tool, and if the purpose of the exercise test is to diagnose ischemia, it should be performed, if possible, in the absence of antianginal medications, particularly long-acting beta-blocking agents, which should be omitted for 2 to 3 days before testing. For long-acting nitrates, calcium antagonists, and short-acting beta blockers, discontinuing use of the medications the day before testing usually suffices.

Nuclear Cardiology Techniques (See Chapter 16)

Stress Myocardial Perfusion Imaging. Exercise myocardial perfusion imaging (MPI) with simultaneous ECG recording is generally considered to be superior to an exercise ECG alone in detecting CAD, in identifying multivessel CAD, in localizing diseased vessels, and in determining the magnitude of ischemic and infarcted myocardium.³¹ Exercise single photon emission computed tomography (SPECT) yields an average sensitivity and specificity of 88% and 72%, respectively (ranges, 71% to 98% and 36% to 92%, respectively), as opposed to 68% sensitivity and 77% specificity for exercise electrocardiography alone (Table 54-2).^{31,32} Referral bias may account, in part, for the low specificity of many studies, and the few studies that have adjusted for referral bias report a specificity higher than 90%. Perfusion imaging is also valuable for detecting myocardial viability in patients with regional or global LV dysfunction, with or without Q waves, and provides important information in regard to prognosis in all patients.

Stress MPI is particularly helpful in the diagnosis of CAD in patients with abnormal resting ECGs and in those in whom ST-segment responses cannot be interpreted accurately, such as patients with repolarization abnormalities caused by LV hypertrophy, those with left bundle branch block, and those receiving digitalis. Because stress MPI is a relatively expensive test (three to four times the cost of an exercise ECG), stress MPI should not be used as a screening test in patients in whom the prevalence of CAD is low because most abnormal test findings will yield false-positive results, and a regular exercise ECG should always be considered first in patients with chest pain and a normal resting ECG for screening and detection of CAD.³²

Myocardial Perfusion Imaging with Pharmacologic Vasodilator Stress. For patients unable to exercise adequately, especially older

adults and those with peripheral vascular disease, pulmonary disease, arthritis, orthopedic problems, severe obesity, or a previous stroke, pharmacologic vasodilator stress with dipyridamole or adenosine derivatives may be used.³³ In most nuclear cardiology laboratories, such patients account for approximately 40% to 50% of those referred for perfusion imaging. Although the diagnostic accuracy of pharmacologic vasodilator stress perfusion imaging is comparable to that achieved with exercise perfusion imaging (Table 54-2), treadmill testing is preferred for patients who are capable of exercising because the exercise component of the test provides additional diagnostic and prognostic information, including ST-segment changes, effort tolerance and symptomatic response, and heart rate and blood pressure response. Vasodilator stress agents are also used with PET to diagnose CAD and determine its severity (see Chapter 16).

Stress Echocardiography (see Chapter 14). Two-dimensional echocardiography is useful for the evaluation of patients with chronic CAD because it can be used to assess global and regional LV function under basal conditions and during ischemia, as well as to detect LV hypertrophy and associated valve disease.³⁴ Stress echocardiography may be performed with exercise or pharmacologic stress and allows detection of regional ischemia by identifying new areas of wall motion disorders. Adequate images can be obtained in more than 85% of patients, and the test is highly reproducible. Numerous studies have shown that exercise echocardiography can detect the presence of CAD with an accuracy similar to that of stress MPI and is superior to exercise electrocardiography alone (Table 54-2). Stress echocardiography is also valuable in localizing and quantifying ischemic myocardium. As with perfusion imaging, stress echocardiography also provides important prognostic information about patients with known or suspected CAD. Pharmacologic stress, such as with dobutamine, should be used in patients unable to exercise, those unable to achieve adequate heart rates with exercise, and those in whom the quality of the echocardiographic images during or immediately after exercise is poor.

Stress echocardiography is an excellent alternative to nuclear cardiology procedures.³⁴ Limitations imposed by poor visualization of endocardial borders in a sizable subset of patients have been reduced by newer techniques, including myocardial contrast perfusion imaging, three-dimensional imaging, and strain-rate echocardiography (see Chapter 14).³⁵ Although less expensive than nuclear perfusion imaging, stress echocardiography is more expensive than and not as widely available as exercise electrocardiography.

Stress Cardiac Magnetic Resonance Imaging and Computed Tomography (See Chapters 17 and 18). Pharmacologic stress perfusion imaging with cardiac magnetic resonance (CMR) also compares favorably with other methods and is being used clinically in some centers, particularly for individuals with limitations in the use of other imaging modalities.³⁶ Stress myocardial computed tomography (CT) perfusion imaging is an emerging technique that provides both anatomic and physiologic information that can be combined with CT angiography in a single protocol with a radiation dose similar to that of nuclear perfusion imaging.³⁷

Clinical Application of Noninvasive Testing

Sex Differences in the Diagnosis of Coronary Artery Disease (See Chapter 77). On the basis of earlier studies that indicated a much higher frequency of false-positive stress test results in women than in men, it is generally accepted that electrocardiographic stress testing is not as reliable in women.³⁸ However, the prevalence of CAD in women in the patient populations under study was low, and the lower positive predictive value of an exercise ECG in women can be accounted for, in large part, on the basis of bayesian principles (see

Table 54-1). Once men and women are stratified appropriately according to the pretest prevalence of disease, the results of stress testing are similar, although the specificity is probably slightly less in women. Exercise imaging modalities have greater diagnostic accuracy than does exercise electrocardiography in men and women. Nevertheless, the standard exercise stress test is recommended by cardiac professional societies as the initial stress test of choice in most patients who can exercise, including women.³⁸ A trial of symptomatic women randomly assigned to exercise ECG or SPECT perfusion imaging demonstrated no difference in the 2-year rate of adverse cardiac events but significantly lower costs with the exercise ECG strategy.³⁹

Identification of Patients at High Risk. When applying noninvasive tests to the diagnosis and management of CAD, it is useful to grade the results as negative; indeterminate; positive, not high risk; or positive, high risk. The criteria for high-risk findings on stress electrocardiography, MPI, and stress echocardiography are listed in Table 54-3.

Regardless of the severity of symptoms, patients with high-risk noninvasive test results have a high likelihood of CAD and, if they have no obvious contraindications to revascularization, should undergo coronary arteriography.⁴⁰ Such patients, even if asymptomatic, are at risk for left main or triple-vessel CAD, and many have impaired LV function. By contrast, patients with clearly negative exercise test results, regardless of symptoms, have an excellent prognosis that cannot usually be improved by revascularization. If they do not have other high-risk features or refractory symptoms, coronary arteriography is not generally indicated. Similarly, patients in whom objective evidence of mild ischemia (e.g., 1-mm ST-segment depression) develops at a high workload (e.g., >9 to 10 minutes on a Bruce protocol) may not necessarily warrant coronary arteriography before an adequate trial of medical therapy is first administered.

Asymptomatic Persons. Exercise testing in asymptomatic individuals without known CAD is not usually recommended. Exercise testing may be appropriate for asymptomatic individuals with diabetes mellitus who plan to begin vigorous exercise, those with high-risk professions (such as airline pilots), and those with evidence of myocardial ischemia on other noninvasive testing, such as severe coronary calcifications on cardiac CT (see Chapter 18).

Chest Roentgenography (See Chapter 15)

The chest roentgenogram is generally within normal limits in patients with SIHD, particularly if they have normal findings on the resting ECG and have not experienced MI. If cardiomegaly is present, it is indicative of severe CAD with previous MI, preexisting hypertension, or an associated nonischemic condition such as concomitant valvular heart disease or cardiomyopathy.

Computed Tomography (See Chapter 18)

Cardiac CT has made substantial advances as a noninvasive approach to imaging atherosclerosis and its consequences.⁴¹ In addition to being a highly sensitive method for detecting coronary calcification, which is a good marker of the total coronary atherosclerotic burden, cardiac CT can also provide angiography of the coronary arterial tree, assessment of myocardial perfusion, and quantification of ventricular function and myocardial viability as an emerging application.^{41,42}

Although coronary calcification is a highly sensitive (≈90%) finding in patients with CAD, its specificity for identifying patients with obstructive CAD is low (≈50%). In view of this limitation, CT is currently *not* recommended as a *routine* approach to screening for obstructive CAD in individuals at low risk for IHD (<10% 10-year estimated risk for coronary events).⁴³ However, selective screening of individuals at intermediate risk for CAD events may be reasonable to consider because a high calcium score may reclassify an individual as being at higher risk and thereby lead to more intense risk factor modification.⁴³ In patients with known CAD, exercise testing is preferable to CT in guiding decisions for coronary angiography.

CT technology has progressed such that in selected individuals, high-quality images of the coronary arteries may be obtained. Consequently, CT angiography may be reasonable in symptomatic patients at intermediate risk for CAD after initial evaluation, in particular, those with indeterminate results of stress testing.^{44,45} In experienced centers with advanced technology, CT has also been used to

TABLE 54-3 Risk Stratification Based on Noninvasive Testing

High Risk (>3% Annual Risk for Death or Myocardial Infarction)	
1.	Severe resting left ventricular dysfunction (LVEF <35%) not readily explained by noncoronary causes
2.	Resting perfusion abnormalities involving ≥10% of the myocardium without previous known MI
3.	High-risk stress findings on the ECG, including <ul style="list-style-type: none"> • ≥2-mm ST-segment depression at low workload or persisting into recovery • Exercise-induced ST-segment elevation • Exercise-induced VT/VF
4.	Severe stress-induced LV dysfunction (peak exercise LVEF <45% or drop in LVEF with stress ≥10%)
5.	Stress-induced perfusion abnormalities encumbering ≥10% of the myocardium or stress segmental scores indicating multiple vascular territories with abnormalities
6.	Stress-induced LV dilation
7.	Inducible wall motion abnormality (involving >2 segments or 2 coronary beds)
8.	Wall motion abnormality developing at a low dose of dobutamine (≤10 mg/kg/min) or at a low heart rate (<120 beats/min)
9.	CAC score >400 Agatston units
10.	Multivessel obstructive CAD (≥70% stenosis) or left main stenosis (≥50% stenosis) on CCTA
Intermediate Risk (1-3% Annual Risk for Death or Myocardial Infarction)	
1.	Mild to moderate resting LV dysfunction (LVEF of 35% to 49%) not readily explained by noncoronary causes
2.	Resting perfusion abnormalities involving 5-9.9% of the myocardium in patients without a history or previous evidence of MI
3.	≥1-mm ST-segment depression occurring with exertional symptoms
4.	Stress-induced perfusion abnormalities encumbering 5-9.9% of the myocardium or stress segmental scores (in multiple segments) indicating 1 vascular territory with abnormalities but without LV dilation
5.	Small wall motion abnormality involving 1-2 segments and only 1 coronary bed
6.	CAC score of 100-399 Agatston units
7.	1-vessel CAD with ≥70% stenosis or moderate CAD stenosis (50-69% stenosis) in ≥2 arteries on CCTA
Low Risk (<1% Annual Risk for Death or Myocardial Infarction)	
1.	Low-risk treadmill score (score ≥5) or no new ST-segment changes or exercise-induced chest pain symptoms when achieving maximal levels of exercise
2.	Normal or small myocardial perfusion defect at rest or with stress encumbering ≥5% of the myocardium*
3.	Normal stress or no change in limited resting wall motion abnormalities during stress
4.	CAC score <100 Agatston units
5.	No coronary stenosis >50% on CCTA

*Although the published data are limited, patients with these findings will probably not be at low risk in the presence of either a high-risk treadmill score or severe resting LV dysfunction (LVEF <35%).

CAC = coronary artery calcium; CCTA = cardiac computed tomography angiography; LVEF = left ventricular ejection fraction; VF = ventricular fibrillation; VT = ventricular tachycardia.

From Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACCP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *Circulation*. 126:e354, 2012.

characterize plaque composition and, when paired with PET in a hybrid PET/CT scanner, can offer an assessment of coronary anatomy concurrent with information regarding myocardial blood flow and metabolism.^{46,47} Nevertheless, in most individuals at present, the temporal resolution of coronary CT angiography is lower than optimal for accurate, complete coronary artery depiction because of nonevaluable segments and limited accuracy in estimating the degree of luminal stenosis. The capacity of CT for determination of plaque composition is also currently not sufficient for routine application.⁴⁴

Therefore, currently, the clinical strength of CT angiography remains its ability to exclude significant CAD with a high negative predictive value.⁴¹ The results of ongoing investigation and new technologic innovations will guide evolution of the role of cardiac CT in the future assessment and management of SIHD.

Cardiac Magnetic Resonance Imaging (See Chapter 17)

CMR is established as a valuable clinical tool for imaging the aorta and cerebral and peripheral arterial vasculature and is evolving as a versatile noninvasive cardiac imaging modality that has multiple applications in patients with IHD.^{44,48} Clinical use of CMR for assessment of myocardial viability has grown because of evidence demonstrating its ability to predict functional recovery after percutaneous or surgical revascularization and its very good correlation with PET. Pharmacologic stress perfusion imaging with CMR compares favorably with SPECT and also offers accurate characterization of LV function, as well as delineation of patterns of myocardial disease that are often useful in discriminating ischemic from nonischemic myocardial dysfunction.⁴⁹

Because of its ability to visualize arteries in three dimensions and differentiate tissue constituents, CMR has received interest as a method to characterize arterial atheroma and assess vulnerability to rupture on the basis of compositional analysis. Characterization of arterial plaque has been achieved in the aorta and carotid arteries in humans and has been shown to be predictive of subsequent vascular events.^{44,50} Moreover, CMR coronary angiography in humans is established as a modality to characterize congenital coronary anomalies (see Chapters 20 and 62) and has shown promise in detecting stenoses in the proximal and middle segments of major epicardial vessels or surgical bypass grafts. Accordingly, CMR is continuing to develop as a single approach for assessment of cardiac function, structure, blood flow, and viability without exposing the patient to ionizing radiation.

Catheterization, Angiography, and Coronary Arteriography

The clinical examination and noninvasive techniques described earlier are extremely valuable in establishing the diagnosis of CAD and are indispensable to the overall assessment of patients with this condition. Currently, however, definitive diagnosis of CAD and precise assessment of its anatomic severity still require cardiac catheterization and coronary arteriography (see Chapters 19 and 20). Nevertheless, it should not be forgotten that myocardial ischemia may occur in the absence of epicardial CAD (see *Chest Pain with a Normal Coronary Arteriogram*).^{1,2} In patients with chronic stable angina referred for coronary arteriography, approximately 25% each have single-, double-, or triple-vessel anatomically significant CAD (i.e., >70% luminal diameter narrowing). Five percent to 10% have obstruction of the left main coronary artery, and in at least 15% and as high as 30% in some series, no critical obstruction is detectable. Advanced invasive imaging techniques such as intravascular ultrasonography (IVUS) provide a cross-sectional view of the coronary artery and have substantially enhanced the detection and quantification of coronary atherosclerosis, as well as the potential to characterize the vulnerability of coronary atheroma (see Chapter 20).⁵¹ Studies incorporating both coronary angiography and IVUS have demonstrated that the severity of CAD may be underestimated by angiography alone. Intravascular optical coherence tomography, angioscopy, and thermography are evolving as additional tools for more complete characterization of coronary atheroma.⁵²⁻⁵⁴ Moreover, studies of coronary flow reserve (maximum flow divided by resting flow) and endothelial function frequently produce abnormal results in patients with CAD and can play an important role in determining the functional significance of a stenosis or in detecting microvascular dysfunction in those without obstructive epicardial disease.^{55,56} These techniques are discussed in Chapters 49 and 55 (see also *Patient Selection for Revascularization*).

Coronary angiographic findings differ between patients with acute MI and those with SIHD. Patients with unheralded MI have fewer

diseased vessels, fewer stenoses and chronic occlusions, and less diffuse disease than do patients with chronic stable angina, thus suggesting that the pathophysiologic substrate and propensity for thrombosis differ between these two groups of patients. In patients with SIHD who have a history of previous MI, total occlusion of at least one major coronary artery is more common than in those without such a history.

Coronary Artery Ectasia and Aneurysms. Patulous aneurysmal dilation involving most of the length of a major epicardial coronary artery is present in approximately 1% to 3% of patients with obstructive CAD at autopsy or angiography. This angiographic lesion does not appear to affect symptoms, survival, or the incidence of MI. Most coronary artery ectasia and/or aneurysms are caused by coronary atherosclerosis (50%), and the rest are caused by congenital anomalies and inflammatory conditions such as Kawasaki disease.⁵⁷ Despite the absence of overt obstruction, 70% of patients with multivessel fusiform coronary artery ectasia or aneurysms have demonstrated evidence of cardiac ischemia based on cardiac lactate levels during ergometry and atrial pacing.

Coronary ectasia should be distinguished from discrete coronary artery aneurysms, which are almost never found in arteries without severe stenosis, are most common in the left anterior descending (LAD) coronary artery, and are usually associated with extensive CAD. These discrete atherosclerotic coronary artery aneurysms do not appear to rupture, and they do not warrant resection.

Coronary Collateral Vessels (See Chapter 20). Provided that they are of adequate size, collateral vessels may protect against MI when total occlusion occurs. In patients with abundant collateral vessels, MI size is smaller than in patients without collaterals, and total occlusion of a major epicardial artery may not lead to LV dysfunction. In patients with chronic occlusion of a major coronary artery but without MI, collateral-dependent myocardial segments show almost normal baseline blood flow and O₂ consumption but severely limited flow reserve. This finding helps explain the ability of collateral vessels to protect against resting ischemia but not against exercise-induced angina.

Myocardial Bridging. Bridging of coronary arteries (see Chapter 20) is observed during coronary angiography at a rate of less than 5% in otherwise angiographically normal coronary arteries and ordinarily does not constitute a hazard. Occasionally, compression of a portion of a coronary artery by a myocardial bridge can be associated with clinical manifestations of myocardial ischemia during strenuous physical activity and may even result in MI or initiate malignant ventricular arrhythmias. In an autopsy study, increased myocardial bridge thickness and length, as well as proximal vessel location, correlated with increased risk for MI, proposed to be due to promotion of proximal atherosclerosis.⁵⁸ The functional consequences of myocardial bridging may be characterized with intracoronary Doppler measurements. Some have found MPI to be useful as well.⁵⁹

Left Ventricular Function. LV function can be assessed by means of biplane contrast ventriculography (see Chapter 20). Global abnormalities in LV systolic function are reflected by elevations in LV end-diastolic and end-systolic volume and depression of the ejection fraction. These changes are, however, nonspecific and can occur in many forms of heart disease. Abnormalities in regional wall motion (e.g., hypokinesis, akinesis, dyskinesis) are more characteristic of CAD. LV relaxation may be impaired at rest in patients with SIHD, and the frequency of elevated LV end-diastolic pressure and reduced cardiac output at rest, generally attributed to abnormal LV dynamics, increases with the number of vessels exhibiting critical narrowing and with the number of previous MIs. LV end-diastolic pressure may be elevated secondary to reduced LV compliance, LV systolic failure, or a combination of these two processes.

Myocardial Metabolism. Cardiac catheterization can also be used to document abnormal myocardial metabolism in patients with SIHD. With a catheter in the coronary sinus, arterial and coronary venous lactate measurements are obtained at rest and after suitable stress, such as the infusion of isoproterenol or pacing-induced tachycardia. Because lactate is a byproduct of anaerobic glycolysis, its production by the heart with subsequent appearance in coronary sinus blood is a reliable sign of myocardial ischemia.

Natural History and Risk Stratification

In a registry of patients with a history of stable angina managed in general practices, 29% experienced angina one or more times per week along with associated greater physical limitation and worse

quality of life. The frequency of reported angina varied substantially between clinics, thus suggesting significant heterogeneity in the success of identifying and managing angina.⁶⁰ Women have a similar incidence of stable angina as men, and angina in both sexes is associated with higher risk for mortality than in the general population. Data from the Framingham Study, obtained before the widespread use of aspirin, beta-blocking agents, and aggressive modification of risk factors, revealed an average annual mortality rate of 4% in patients with SIHD. The combination of these treatments has improved the prognosis, with an annual mortality rate of 1% to 3% and a rate of major ischemic events of 1% to 2%. For example, among 38,602 outpatients with SIHD enrolled in 2003 to 2004, the 1-year rate of cardiovascular death was 1.9% (95% confidence interval [CI], 1.7% to 2.1%), that of all-cause mortality was 2.9% (95% CI, 2.6% to 3.2%), and that of cardiovascular death, MI, or stroke was 4.5% (95% CI, 4.2% to 4.8%).⁶¹ Clinical, noninvasive, and invasive tools are useful for refining the estimated risk in individual patients with SIHD. Moreover, noninvasively acquired information is valuable in identifying patients who are candidates for invasive evaluation with cardiac catheterization.

Clinical Criteria

Clinical characteristics, including age, male sex, diabetes mellitus, previous MI, and the presence of symptoms typical of angina, are predictive of the presence of CAD.⁶² A number of studies have attested to the adverse prognostic implications of heart failure in patients with SIHD. The severity of angina, especially the tempo of intensification, and the presence of dyspnea are also important predictors of outcome.⁶²

Noninvasive Testing (see Chapters 13, 14, and 16)

Exercise Electrocardiography

The prognostic importance of the treadmill exercise test was determined by observational studies in the 1980s and early 1990s. One of the most important and consistent predictors is maximal exercise capacity, regardless of whether it is measured by exercise duration or by workload achieved or whether the test was terminated because of dyspnea, fatigue, or angina.⁶ After adjustment for age, the peak exercise capacity measured in metabolic equivalents is among the strongest predictors of mortality in men with cardiovascular disease.⁶³ Other factors associated with a poor prognosis in patients with SIHD are delineated in Table 54-3.

Stress Nuclear Myocardial Perfusion Imaging (see Chapter 16)

The prognostic value of stress MPI is now well established. In particular, the ability of myocardial perfusion SPECT to identify patients at low (<1% with a normal MPI study), intermediate (1% to 5%), or high (>5%) risk for future cardiac events is valuable in patient management decisions. The prognostic data obtained from myocardial perfusion SPECT are incremental to clinical and treadmill exercise data in predicting future cardiac events.⁶⁴

Echocardiography

Assessment of LV function is one of the most valuable aspects of echocardiography. Such testing is not necessary for all patients with angina pectoris, and in patients with normal ECGs and no previous history of MI, the likelihood of preserved LV systolic function is high. In contrast, in patients with a history of MI, ST-T wave changes, or conduction defects or Q waves on the ECG, LV function should be measured via echocardiography or an equivalent technique. The presence or absence of inducible regional wall motion abnormalities and the response of the ejection fraction to exercise or pharmacologic stress appear to provide incremental prognostic information to that provided by the resting ECG. Moreover, a negative stress echocardiographic result portends a low risk for future events (<1% per person-year).

Angiographic Criteria. The independent impact of multivessel CAD and LV dysfunction and their interaction on the prognosis of

FIGURE 54-4 Graphs showing survival of medically treated patients in CASS stratified by normal, moderately, or severely reduced left ventricular ejection fraction (LVEF). **A**, Patients with single-vessel coronary disease. **B**, Patients with double-vessel coronary disease. **C**, Patients with triple-vessel coronary disease. (From Ermon M, Mock MB, Davis KB, et al: Long-term survival of medically treated patients in the Coronary Artery Surgery Study [CASS] Registry. *Circulation* 90:2651, 1994.)

patients with CAD is well established (Fig. 54-4). However, manifestations of CAD in the absence of obstructive atherosclerosis are now recognized and have been associated with an adverse prognosis.^{1,2}

Extent of Coronary Artery Disease. Although several indices have been used to quantify the extent or severity of CAD, the simple classification of disease into single-, double-, or triple-vessel or left main CAD is the most widely used and is effective. Additional prognostic information is provided by the severity of the obstruction and its location, whether proximal or distal. The concept of the gradient of risk is illustrated in Figure 54-5. The importance to survival of the quantity of myocardium that is jeopardized is reflected in the observation that an obstructive lesion proximal to the first septal perforating branch of the LAD coronary artery was associated with a 5-year survival rate of 90%, as opposed to 98% in patients with more distal lesions. Scoring systems to capture more detailed assessment of the

full extent and severity of epicardial CAD, such as the SYNTAX (Synergy between PCI with Taxus and Cardiac Surgery) score, have been developed and validated.⁶⁵

High-grade lesions of the left main coronary artery or its equivalent, as defined by severe proximal LAD and proximal left circumflex CAD, are particularly life-threatening. Mortality in medically treated patients has been reported to be 29% at 18 months and 43% at 5 years. Survival is better in patients with 50% to 70% stenosis (1- and 3-year survival rates of 91% and 66%, respectively) than in patients with a left main coronary artery stenosis greater than 70% (1- and 3-year survival rates of 72% and 41%, respectively), especially in those with preserved LV systolic function.

Limitations of Angiography. Coronary angiography provides information principally about the degree of luminal stenosis of the coronary arteries. The pathophysiologic significance of coronary stenoses lies both in their impact on resting and exercise-induced blood flow and in their potential for plaque rupture with superimposed thrombotic occlusion. It is generally accepted that a stenosis involving more than 60% of the luminal diameter is hemodynamically significant in that it may be responsible for a reduction in exercise-induced myocardial blood flow that causes ischemia. The immediate functional significance of obstruction of intermediate severity ($\approx 50\%$ diameter stenosis) is less well established. Coronary angiography is not a reliable indicator of the functional significance of stenosis. Furthermore, coronary angiographic determinants of the severity of stenosis are based on a decrease in the caliber of the lumen at the site of the lesion relative to adjacent reference segments, which are considered, often erroneously, to be relatively free of disease. This approach may lead to significant underestimation of the severity and extent of atherosclerosis.

The most serious limitation to the routine use of coronary angiography for prognosis in patients with SIHD is its inability to identify which coronary lesions can be considered to be at high risk, or vulnerable, for future events, such as MI or sudden death. Although it is widely accepted that MI is the result of thrombotic occlusion at the site of plaque rupture or erosion (see Chapters 41 and 51), it is clear that it is not necessarily the plaque causing the most severe stenosis that subsequently ruptures. Lesions causing mild obstruction can rupture, thrombose, and occlude, thereby leading to MI and sudden death. In fact, two thirds to three quarters of all acute MIs emanate from antecedent coronary stenoses that involve less than 50% of the luminal diameter. Approaches to quantifying the extent of CAD, inclusive of nonobstructive lesions, appear to offer additional prognostic information.⁶⁵

In summary, angiographic documentation of the extent of CAD provides useful information for assessment of the patient's risk for death and future ischemic events and is an indispensable step in the selection of patients for coronary revascularization, particularly if the interaction between the anatomic extent of disease, LV function, and severity of ischemia is taken into account. However, angiography is not helpful in predicting sites of subsequent plaque rupture or erosion that can precipitate MI or sudden cardiac death. Additional tools that improve the imaging of coronary atheroma, such as IVUS (see Chapter 20), or functional assessment of a stenosis, such as determination of the fractional flow reserve (FFR) (see Patient Selection for Revascularization; see also Chapters 49 and 55), can be helpful in deciding on the flow-limiting significance of a specific lesion and the need for coronary revascularization.^{55,56} Characterization of the atheroma and also coronary flow reserve with CT or CMR remains under evaluation but is not yet a routine clinical tool.

Medical Management

Comprehensive management of SIHD has five aspects: (1) identification and treatment of associated diseases that can precipitate or worsen angina and ischemia; (2) reduction of coronary risk factors; (3) application of pharmacologic and nonpharmacologic interventions for secondary prevention, with particular attention directed to adjustments in lifestyle; (4) pharmacologic management of angina; and (5) revascularization by catheter-based percutaneous coronary intervention (PCI) (see Chapter 55) or by coronary artery bypass grafting (CABG), when indicated. Although discussed individually in this chapter, all five of these approaches must be considered, often simultaneously, in each patient. Of the medical therapies, three (aspirin, angiotensin-converting enzyme [ACE] inhibition, and effective lipid lowering) have been shown to reduce mortality and morbidity in patients with SIHD and preserved LV function. Other therapies such as nitrates, beta blockers, calcium antagonists, and ranolazine have been shown to improve symptomatology and exercise performance but their effect, if any, on survival in patients with SIHD has not been demonstrated.

In stable patients with LV dysfunction following MI, evidence has consistently indicated that ACE inhibitors and beta-blocking agents reduce both mortality and the risk for repeat MI, and these agents are recommended in all such patients, with or without chronic angina, along with aspirin and lipid-lowering drugs.

FIGURE 54-5 Angiographic extent of CAD and subsequent survival with medical therapy. A gradient of mortality risk is established based on the number of diseased vessels and the presence and severity of disease of the proximal LAD coronary artery. (Data from Califf RM, Armstrong PW, Carver JR, et al: Task Force 5: Stratification of patients into high-, medium-, and low-risk subgroups for purposes of risk factor management. *J Am Coll Cardiol* 27:964, 1996.)

Treatment of Associated Diseases

Several common medical conditions that can increase myocardial O_2 demand or reduce O_2 delivery may contribute to the onset of new angina pectoris or exacerbation of previously stable angina. Such conditions include anemia, marked weight gain, occult thyrotoxicosis, fever, infections, and tachycardia. Cocaine, which can cause acute coronary spasm and MI, is discussed in Chapter 68. In patients with CAD, heart failure, by causing cardiac dilation, mitral regurgitation, or tachyarrhythmias (including sinus tachycardia), can increase myocardial O_2 need, along with an increase in the frequency and severity of angina. Identification and treatment of these conditions are critical to the management of SIHD.

Reduction of Coronary Risk Factors

Hypertension (See Chapters 43 and 44)

Epidemiologic links between increased blood pressure and CAD severity and

mortality are well established. For individuals 40 to 70 years of age, risk for IHD doubles for each 20-mm Hg increment in systolic blood pressure across the entire range of 115 to 185 mm Hg.⁶⁶ Hypertension predisposes to vascular injury, accelerates the development of atherosclerosis, increases myocardial O₂ demand, intensifies ischemia in patients with preexisting obstructive CAD, and predisposes to atrial fibrillation. Although the relationship between hypertension and CAD is linear, LV hypertrophy is a stronger predictor of MI and CAD death than is the actual degree of increase in blood pressure.⁶⁶ A meta-analysis of clinical trials of treatment of mild to moderate hypertension has shown a statistically significant 16% reduction in CAD events and mortality in patients receiving antihypertensive therapy. This treatment effect is almost twice as great in older as in younger persons. It is logical to extend these observations about the benefits of antihypertensive therapy to patients with established CAD. Moreover, the number of individuals treated to avoid one death is lower in subjects with established cardiovascular disease. Therefore blood pressure control is an essential component of the management of patients with SIHD, with a goal of less than 140/90 mm Hg.^{67,68} Additionally, patients with refractory hypertension should be receiving two or more medications for optimal blood pressure control.⁶⁶ Newer and emerging options for the treatment of hypertension are discussed in [Chapter 44](#).⁶⁹ Although there has been an assumed incremental risk for increased cardiovascular events in hypertensive patients with IHD and diabetes and a belief that more intensive blood pressure lowering would reduce clinical events, the ACCORD-BP study did not reveal an additional benefit of lowering systolic blood pressure below 120 mm Hg in persons with type 2 diabetes mellitus as compared with lowering blood pressure to less than 140 mm Hg.⁷⁰

Cigarette Smoking

Smoking remains one of the most powerful risk factors for the development of CAD in all age groups ([see Chapter 42](#)). In patients with angiographically documented CAD, cigarette smokers have a higher 5-year risk for sudden death, MI, and all-cause mortality than do those who have stopped smoking. Cigarette smoking may be responsible for aggravating angina other than through the progression of atherosclerosis. It may increase myocardial O₂ demand and reduce coronary blood flow by means of an alpha-adrenergically mediated increase in coronary artery tone and thereby cause acute ischemia. Moreover, passive exposure to cigarette smoke has adverse cardiovascular effects that are almost as large as those of active smoking. Smoking cessation lessens the risk for adverse coronary events in patients with established CAD and is one of the most effective and cost-saving approaches to prevention of disease progression in native vessels and bypass grafts.^{67,71} Strategies for smoking cessation are discussed in [Chapter 47](#).

Management of Dyslipidemia (See Chapter 45)

Clinical trials in patients with established atherosclerotic vascular disease have demonstrated a significant reduction in subsequent cardiovascular events in patients with a wide range of serum cholesterol and LDL cholesterol levels treated with statins. In the aggregate, angiographic trials of cholesterol lowering in patients with chronic CAD have shown that its effects on coronary obstruction are modest in comparison to the substantive reduction in cardiovascular events, thus suggesting that regression of atherosclerosis is not the primary mechanism of benefit. Nonetheless, in angiographic trials using IVUS, intensive statin therapy has led to regression of coronary atherosclerotic burden in patients with angiographic CAD. Furthermore, several, but not all studies have shown that statins significantly improve endothelium-mediated responses in the coronary and systemic arteries of patients with hypercholesterolemia or known atherosclerosis.

Lipid lowering to reduce elevated levels of LDL with statins has been shown to reduce circulating levels of hsCRP, decrease thrombogenicity, and favorably alter the collagen and inflammatory components of arterial atheroma; these effects do not appear to correlate well with the change in serum LDL cholesterol level and suggest antiatherothrombotic properties of statins. These pleiotropic

properties may contribute to plaque stabilization, improvement in blood flow, reduction of inducible myocardial ischemia, and a decrease in coronary events in patients treated with statins.

Results from secondary prevention trials of patients with a history of SIHD, unstable angina, or previous MI have provided convincing evidence that effective lipid-lowering therapy significantly improves overall survival and reduces cardiovascular mortality in patients with CAD, regardless of baseline cholesterol levels. Moreover, results from trials of intensive- versus moderate-dose statin therapy in patients with established IHD have provided evidence of a reduction in major cardiovascular events with more aggressive lipid-lowering therapy with achieved LDL concentrations of less than 100 mg/dL ([Fig. 54-6](#)). The National Cholesterol Education Program Guidelines ([see Chapter 45](#)) advocated cholesterol-lowering therapy in all patients with CAD or extracardiac atherosclerosis to LDL levels below 100 mg/dL, and these guidelines were adopted in prior recommendations from the American College of Cardiology/American Heart Association (ACC/AHA).⁶⁷ The 2013 ACC/AHA guidelines for cholesterol management advocate high-intensity statin therapy in all patients with established IHD who are less than 75 years of age, in the absence of contraindications, with less emphasis on LDL target goals.^{72,73}

LOW HIGH-DENSITY LIPOPROTEIN CHOLESTEROL. Patients with established CAD and low levels of HDL cholesterol represent a subgroup at considerable risk for future coronary events, even when LDL cholesterol is low.⁷⁴ Low HDL levels are often associated with obesity, hypertriglyceridemia, and insulin resistance. The constellation of these findings—often referred to as metabolic syndrome—typically signifies the presence of small lipoprotein remnants and small, dense, LDL particles, which are thought to be particularly atherogenic ([see Chapter 45](#)). Therapy has focused on diet and exercise, as well as on LDL cholesterol reduction together with a concomitant increase in HDL cholesterol levels. The VA-HIT (Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial) study group demonstrated the efficacy of gemfibrozil treatment in patients with low HDL cholesterol (≤ 40 mg/dL) without elevations in LDL cholesterol (≤ 140 mg/dL) or triglyceride levels (mean, 160 mg/dL) and who were not treated with a statin. Gemfibrozil resulted in a 6% increase in HDL cholesterol and a 31% decrease in triglyceride levels, and these changes were associated with a 24% reduction in death, nonfatal MI, and stroke. However, a subsequent randomized trial of extended-release niacin versus placebo in 3414 patients with atherosclerotic vascular disease who had low baseline levels of HDL (< 40 mg/dL for men; < 50 mg/dL for women) and well-controlled LDL cholesterol values (< 70 mg/dL) while taking a statin, with or without ezetimibe, found no incremental clinical benefit of the addition of niacin to statin therapy during a mean 3-year follow-up.⁷⁵ In addition, a secondary prevention trial involving 25,673 IHD patients (Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events) reported no significant reduction in a composite of major vascular events during a mean 4 years of treatment with simvastatin combined with extended-release niacin and laropiprant, a prostaglandin D₂ receptor-1 antagonist used to retard cutaneous flushing during niacin therapy, as compared with statin-based therapy alone.⁷⁶ Emerging therapies aimed at promoting reverse cholesterol transport and/or interfering with HDL metabolism to raise the concentration of HDL or the apolipoprotein A-I concentration (the main protein in HDL) are under investigation.⁷⁷ In two large randomized trials, torcetrapib, a cholesteryl ester transfer protein (CETP) inhibitor, increased HDL cholesterol by 61% and reduced LDL cholesterol by 20% but did not decrease progression of atherosclerosis and was associated with an increase in ischemic events, which may be explained by an increase in blood pressure with torcetrapib.⁷⁸ In addition, a large outcomes trial of the CETP inhibitor dalcetrapib was stopped early because of a reported lack of clinically meaningful efficacy.⁷⁸ Even though CETP inhibitors may raise plasma levels of HDL significantly, these agents can produce qualitatively dysfunctional large HDL particles that may not be associated with a reduction in cardiac events. These trials have raised questions regarding the treatment of HDL cholesterol as a target for secondary prevention.⁷⁸

Management of Diabetes Mellitus (See Chapter 61). Patients with diabetes mellitus are at significantly higher risk for atherosclerotic vascular disease. Although a favorable impact of control of glycemia on microvascular complications of diabetes has been established, the effect on macrovascular complications (including CAD) is unclear. During a mean follow-up of 17 years in participants in the Diabetes Control and Complications Trial, patients with type 1 diabetes assigned to intensive glycemic therapy were at lower risk for cardiovascular complications. However, the results of studies of glycemic therapy with a shorter duration of follow-up, principally in subjects with type 2 diabetes, are mixed.⁷⁹ Several large trials evaluating the effects of oral hypoglycemic agents on cardiovascular outcomes have shown no reduction in major cardiovascular events.^{79a,79b} Weight management, physical activity, blood pressure control, and lipid management are recommended for all patients with SIHD and diabetes.⁶⁷

Estrogen Replacement. In view of the collective data from randomized clinical trials, it is *not* advised that hormone replacement therapy be initiated or continued for secondary cardiovascular prevention in women with CAD (see Chapter 77).⁶⁷

Exercise (see Chapter 47)

The conditioning effect of exercise on skeletal muscles allows a greater workload at any level of total-body O₂ consumption. By

decreasing the heart rate at any level of exertion, higher cardiac output can be achieved at any level of myocardial O₂ consumption. The combination of these two effects of exercise conditioning permits patients with chronic stable angina to increase physical performance substantially following institution of a continuing exercise program.⁸⁰

Most of the information about the physiologic effects of exercise and their effect on prognosis in patients with CAD has come from studies on patients entered into cardiac rehabilitation programs, many of whom previously sustained an MI. Less information is available on the benefits of exercise in patients with SIHD without a previous MI. Collectively, small randomized trials evaluating exercise training in patients with SIHD indicate improved effort tolerance, O₂ consumption, and quality of life and reduced evidence of ischemia on MPI.⁸⁰ Small randomized studies of exercise training have shown fewer hospitalizations and revascularization procedures in those allocated to regular exercise, as well as favorable changes in inflammatory and hemostatic mediators of cardiovascular risk in proportion to the intensity of exercise.⁸¹ Whether exercise accelerates the development of collateral vessels in patients with chronic CAD is unclear.

Exercise is safe if begun under supervision and increased gradually,⁸² and if survivors of MI can be used as a yardstick, it is probably cost-effective. The psychological benefits of exercise are difficult to evaluate. However, a single nonrandomized study demonstrated significant improvement in well-being scores and positive affect scores, as well as a reduction in disability scores, in patients in a structured exercise program. Patients who are involved in exercise programs are also more likely to be health conscious, to pay attention to diet and weight, and to discontinue cigarette smoking. For all these reasons, patients should be urged to participate in regular exercise programs, usually walking, in conjunction with their drug therapy.^{67,80,83}

Obesity (See Chapter 42 and 61)

Obesity is both an independent contributor to the risk for IHD and is associated with a constellation of other risk factors, including hypertension, dyslipidemia, and abnormal glucose metabolism. Weight loss can improve or prevent many of the cardiovascular consequences of obesity.^{80,84}

Inflammation (See Chapters 41 and 42)

Atherothrombosis has been recognized as an inflammatory disease.⁸⁵ Markers of systemic inflammation, of which hsCRP is the most extensively studied, identify patients with established vascular disease who are at higher risk for death and future ischemic events. Moreover, the lower levels of hsCRP achieved with statin therapy in patients with established IHD are associated with a better long-term prognosis.⁶ Targeting of inflammation as a potential objective for therapeutic intervention in patients with IHD is discussed in Chapters 41 and 45. Additional research is ongoing to clarify whether inflammation should be a target for routine strategies of risk reduction or novel therapeutic agents in patients with atherosclerosis.^{86,87}

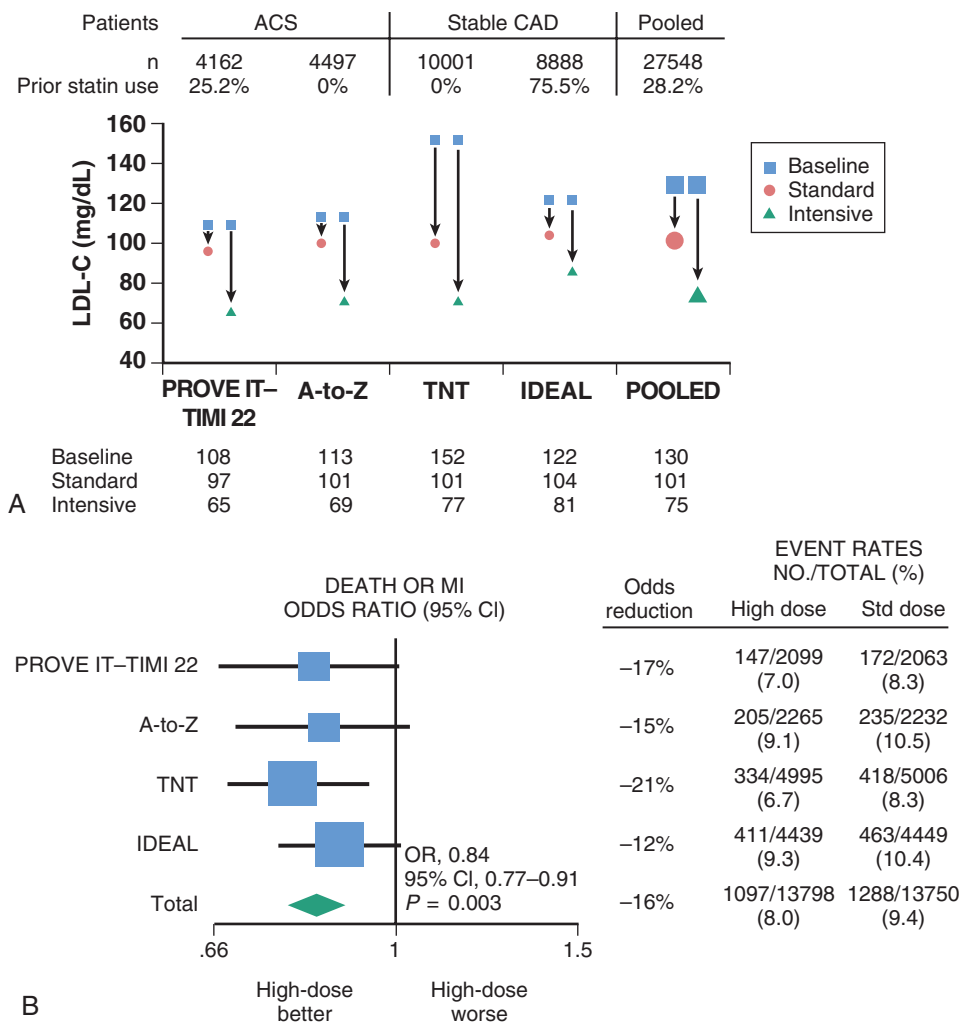

FIGURE 54-6 Pooled evaluation of intensive versus standard statin therapy for patients with established CAD in the PROVE IT-TIMI 22 trial (Pravastatin or Atorvastatin Evaluation and Infection Therapy; atorvastatin, 80 mg daily, versus pravastatin, 40 mg daily), A-to-Z trial (Aggrastat-to-Zocor; simvastatin, 40 mg daily for 30 days followed by 80 mg daily, versus placebo for 4 months, followed by simvastatin, 20 mg daily), TNT trial (Treat to New Targets; atorvastatin, 80 mg daily, versus atorvastatin, 10 mg daily), and IDEAL trial (Incremental Decrease in Endpoints Through Aggressive Lipid-Lowering; atorvastatin, 80 mg daily, versus simvastatin, 20 mg daily). Intensive statin therapy was associated with significantly lower achieved levels of LDL cholesterol (LDL-C; **A**) and 16% lowering of the risk for death or MI (**B**). OR = odds ratio. (From Cannon CP, Steinberg BA, Murphy SA, et al: Meta-analysis of cardiovascular outcomes trials comparing intensive versus moderate statin therapy. *J Am Coll Cardiol* 48:438, 2006.)

Pharmacotherapy for Secondary Prevention

Aspirin (See Chapters 42, 52, and 82). A meta-analysis of 140,000 patients in 300 studies has confirmed the prophylactic benefit of aspirin in men and women with angina pectoris, with previous MI or stroke, and after CABG. In a Swedish trial of men and women with chronic stable angina, 75 mg of aspirin in conjunction with the beta-blocking agent sotalol conferred a 34% reduction in acute MI and sudden death. In a smaller study confined to men with chronic stable angina but without a history of MI, 325 mg of aspirin on alternate days reduced the risk for MI by 87% during 5 years of follow-up. Therefore administration of aspirin daily is advisable in patients with SIHD and no contraindications to this drug. Dosing at 75 to 162 mg daily appears to have comparable effects on secondary prevention as dosing at 160 to 325 mg daily and seems to be associated with lower bleeding risk. Thus aspirin, 75 to 162 mg daily, is preferred for secondary prevention in the absence of recent intracoronary stenting.⁶⁷ Although oral anticoagulants appear to be beneficial in patients after MI, no evidence supports the use of chronic anticoagulation in patients with stable angina.

Other Oral Platelet Inhibitors. Other orally acting antiplatelet agents have been studied in patients with SIHD. Clopidogrel, a thienopyridine derivative, may be substituted for aspirin in patients with aspirin hypersensitivity or in those who cannot tolerate aspirin (see Chapter 82).⁶⁷ In a randomized comparison between clopidogrel and aspirin in patients with established atherosclerotic vascular disease (the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events [CAPRIE] trial), treatment with clopidogrel resulted in a modest 8.7% relative reduction in the risk for vascular death, ischemic stroke, or MI ($P = 0.043$) over a period of 2 years. Studies evaluating the addition of clopidogrel to aspirin in patients with non-ST-segment elevation ACS or after PCI have demonstrated robust risk reductions. However, the CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management and Avoidance) trial showed no overall benefit of the addition of clopidogrel to aspirin with respect to the primary endpoint of cardiovascular death, MI, or stroke over a median of 28 months in patients with clinically evident cardiovascular disease ($n = 12,153$) or in asymptomatic subjects with multiple risk factors ($n = 3284$). In the large subgroup of those with established vascular disease, the addition of clopidogrel was associated with a one percentage point lower risk for these events (6.9% versus 7.9%; $P = 0.046$), thus supporting the hypothesis of a potential benefit from clopidogrel in patients with SIHD taking aspirin.⁶⁸ A large study of the investigational oral platelet inhibitor vorapaxar has provided additional support that more potent antiplatelet therapy than aspirin alone is useful for patients with SIHD. In a randomized, double-blinded trial of vorapaxar, an antagonist

of the platelet-activating action of thrombin, versus placebo added to standard therapy, vorapaxar reduced the risk for recurrent major cardiovascular events in patients with previous MI monitored for an average of 2.5 years.^{89,90} However, a significant increase in the risk for bleeding with vorapaxar underscores the need for tailoring treatment to the individual patient based on the competing risks for increased thrombotic events versus increased bleeding. Trials with other oral platelet inhibitors in patients with SIHD are ongoing, as well as trials focused on patients with CAD who have undergone coronary stenting.⁹¹

Beta-Blocking Agents. The value of beta adrenoceptor-blocking drugs (beta-blocking agents) in reducing death and recurrent MI in patients who have experienced MI is well established (see Chapters 52 and 53), as is their usefulness in the treatment of angina. Whether these drugs are also of value in preventing MI and sudden death in patients with SIHD without previous MI is less certain, and there have been no prospective controlled trials involving placebo. Findings from observational studies are mixed, with one of the largest studies reporting no reduction in mortality in patients with SIHD receiving beta-blocking agents (Fig. 54-7).⁹² However, there is no reason to assume that the favorable effects of beta blockers on ischemia and perhaps on arrhythmias should not apply to patients with SIHD. In addition, observational data have raised the possibility that beta blockers may reduce progression of coronary atherosclerosis, in part through reduced turbulence and intramural arterial wall stress. Therefore although the use of beta blockers as first-line therapy for uncomplicated hypertension has been questioned, it is sensible to use these drugs when angina, hypertension, or both are present in patients with SIHD and when these drugs are well tolerated.^{67,93} Emerging evidence has also identified genetic polymorphisms of the beta₂-adrenergic receptor gene (*ADRB1* and *ADRB2*) that may influence responsiveness to beta-blocking agents.⁹⁴

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers. Although inhibitors of the renin-angiotensin-aldosterone system are not indicated for the treatment of angina, these drugs appear to have important benefits in reducing the risk for future ischemic events in some patients with cardiovascular disease.⁹⁵ Potentially beneficial effects of ACE inhibitors include reductions in LV hypertrophy, vascular hypertrophy, progression of atherosclerosis, plaque rupture, and thrombosis, in addition to a potentially favorable influence on myocardial O₂ supply-and-demand relationships, cardiac hemodynamics, sympathetic activity, and coronary endothelial vasomotor function. Furthermore, in vitro experiments have shown that angiotensin II induces inflammatory changes in human vascular smooth muscle cells and that treatment with ACE inhibitors can reduce signs of inflammation in animal models of atherosclerosis.

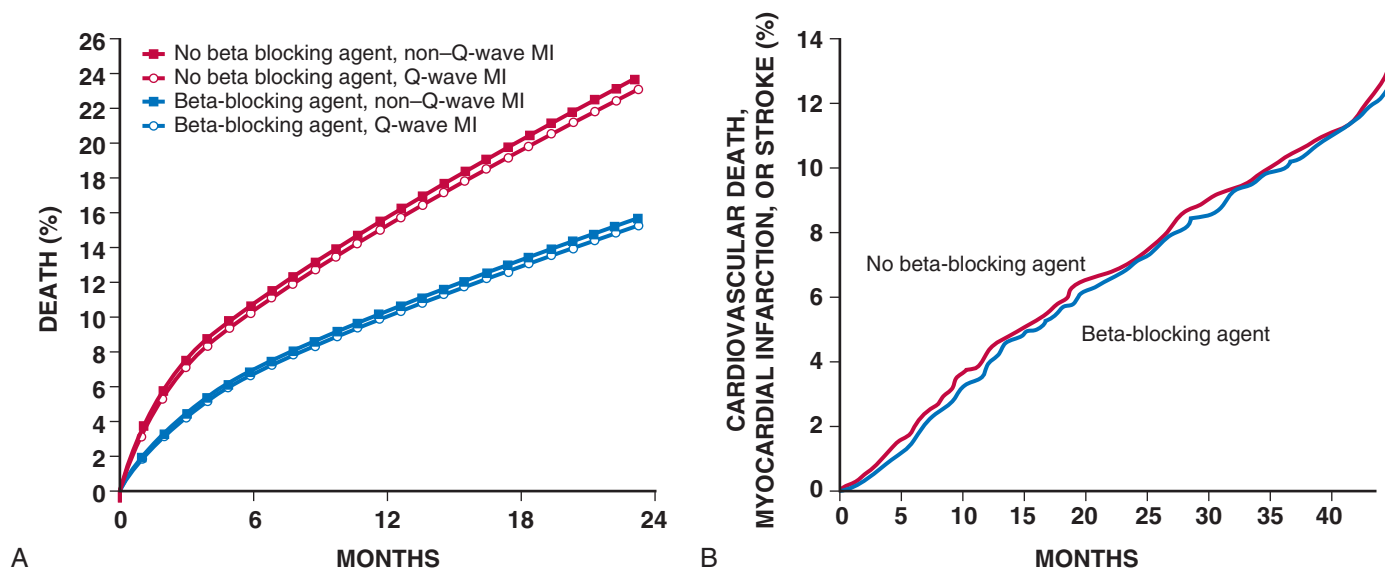

FIGURE 54-7 A, Assessment of the association between administration of a beta-blocking agent and the mortality rate in 201,752 individuals with previous MI followed in a Medicare-based registry of patients discharged in 1994 to 1995 after MI. In patients with uncomplicated MI, prescription of a beta blocker was associated with a 40% relatively lower mortality rate. B, Longitudinal, observational study of patients in the REACH (Reduction of Atherothrombosis for Continued Health) registry in which a subgroup of 12,012 patients with known CAD and no previous MI were monitored. In a propensity-matched analysis, the rate of cardiovascular death, MI, or stroke did not differ between those treated with or without a beta blocker ($n = 3599$ in each matched group; hazard ratio, 0.92; 95% CI, 0.79 to 1.08; $P = 0.31$). (A, From Gottlieb SS, McCarter RJ, Vogel RA: Effect of beta-blockade on mortality among high-risk and low-risk patients after myocardial infarction. *N Engl J Med* 339:493, 1998; B, from Bangalore S, Steg G, Deedwania P, et al: Beta-blocker use and clinical outcomes in stable outpatients with and without coronary artery disease. *JAMA* 308:1340, 2012.)

FIGURE 54-8 Kaplan-Meier time-to-event curves for the primary endpoint of three large randomized, placebo-controlled trials of ACE inhibitors for patients at high risk for or with established cardiovascular disease without heart failure. **A**, Cumulative incidence of cardiovascular death, MI, or stroke with ramipril versus placebo in patients in the HOPE trial. **B**, Cumulative incidence of cardiovascular death, MI, or cardiac arrest with perindopril or placebo in EUROPA. **C**, Cumulative incidence of cardiovascular death, MI, or coronary revascularization in the PEACE trial. **D**, Comparison of cardiovascular death, MI, or stroke in the HOPE and PEACE trials. The cumulative incidence of major cardiovascular events was lower in patients treated with placebo in the PEACE trial than in patients treated with ramipril in the HOPE trial. (**A**, From HOPE Study Investigators: Effects of an angiotensin-converting enzyme inhibitor, ramipril, on cardiovascular events in high risk patients. *N Engl J Med* 342:145, 2000; **B**, from EUROPA Investigators: Efficacy of perindopril in reduction of cardiovascular events among patients with stable coronary artery disease: Randomized double-blind, placebo-controlled, multicenter trial [the EUROPA study]. *Lancet* 363:782, 2003; and **C**, From PEACE Trial Investigators: Angiotensin-converting enzyme inhibition in stable coronary artery disease. *N Engl J Med* 351:2058, 2004.)

Two trials have provided strong evidence supporting the therapeutic benefit of ACE inhibitors in patients with normal LV function and absence of heart failure (Fig. 54-8). In the HOPE (Heart Outcomes Protection Evaluation) study, ramipril significantly decreased the risk for major vascular events by a relative 22% in 9297 patients with atherosclerotic vascular disease or diabetes mellitus. EUROPA (European Trial on Reduction of Cardiac Events with Perindopril in Stable CAD) similarly showed a 20% relative reduction in the risk for cardiovascular death, MI, or cardiac arrest in 13,655 patients with stable CAD in the absence of heart failure. In contrast, in the PEACE (Prevention of Events with Angiotensin Converting Enzyme Inhibition) trial, trandolapril showed no effect on the risk for cardiovascular death, MI, or coronary revascularization in 8290 patients with stable CAD and preserved LV function receiving intensive preventive therapy (Fig. 54-8).⁹⁵ ACE inhibitors are recommended for all patients with CAD and LV dysfunction and for those with hypertension, diabetes, or chronic kidney disease.⁶⁷ ACE inhibitors may be considered for optional use in all other patients with SIHD, a normal LV ejection fraction, and well-controlled cardiovascular risk factors in whom revascularization has been performed.⁶⁷ Investigation aimed at identifying reliable indicators of which patients with SIHD will derive particular benefit from treatment is ongoing; such indicators include renal dysfunction, biomarkers of myocardial stress, and genetic polymorphisms.^{27,96} In patients with established vascular disease or high-risk diabetes, telmisartan, an angiotensin receptor blocker (ARB), was equivalent to ramipril with respect to secondary prevention of major cardiovascular events in patients tolerant of ACE inhibitors but was not superior to placebo in patients intolerant of ACE inhibitors. The combination of telmisartan and ramipril provided no additional benefit over ramipril alone and resulted in an increased rate of complications.⁹⁷

Antioxidants (See Chapter 41). Oxidized LDL particles are strongly linked to the pathophysiology of atherogenesis, and observational studies have suggested that high dietary intake of antioxidant vitamins (A, C, and beta-carotene) and flavonoids (polyphenolic antioxidants), naturally present in vegetables, fruits, tea, and wine, is associated with a decrease in CAD events. However, in multiple large randomized trials of antioxidant supplements, including vitamin E, vitamin C, beta-carotene, folic acid, and vitamins B₆ and B₁₂, the risk for major cardiovascular events was not reduced.⁹⁸ Thus according to current evidence, there is no basis for recommending that individuals with IHD take supplemental folate, vitamin E, vitamin C, or beta-carotene for the purpose of improving cardiovascular outcomes.⁶⁷ Additional investigation of other approaches to antioxidant therapy is ongoing.⁹⁹

Counseling and Changes in Lifestyle

The psychosocial issues faced by patients in whom stable angina develops are similar to, although usually less intense than those experienced by patients with acute MI. Depressive symptoms are strongly associated with health status as reported by the patient, including the burden of symptoms and overall quality of life, independent of LV function and the presence of provokable ischemia.^{100,101} In addition, the association between depressive symptoms and IHD may reflect a causal relationship between the former and atherothrombosis inasmuch as depressive symptoms are associated with higher levels of circulating biomarkers of inflammation.¹⁰² In conjunction with counseling, treatment with a selective serotonin reuptake inhibitor appears to be safe and effective in managing depression in patients with IHD.¹⁰¹ Thus effort to evaluate and treat depression in patients with

CAD is an important element of the overall management of such patients.^{103,104} Moreover, psychosocial stress at work, home, or both is associated with an increased risk for MI and may be a target for preventive interventions.¹⁰⁵ In a small randomized placebo-controlled trial, physical exercise complemented antidepressant pharmacotherapy in reducing depressive symptoms.¹⁰⁶

An important aspect of the physician's role is to counsel patients with respect to dietary habits, goals for physical activity, the types of work that they can do, and their leisure activities.¹⁰⁷ Certain changes in lifestyle may be helpful, such as modifying strenuous activities if they constantly and repeatedly produce angina. A history of CAD and stable angina is not inconsistent with the ability for physical exertion, which is important not only in regard to recreational activities and lifestyle but also for patients in whom some physical exertion is required in their employment. However, isometric activities such as weightlifting and other activities such as snow shoveling, which involves an energy expenditure of between 60% and 65% of peak O₂ consumption, and cross-country or downhill skiing are undesirable. In addition, these latter activities expose the individual to the detrimental effects of cold on the O₂ demand-and-supply relationship, and such activities should also be avoided whenever possible.

Eliminating or reducing the factors that precipitate anginal episodes is of obvious importance. Patients learn their usual threshold by trial and error. Patients should avoid sudden bursts of activity, particularly after long periods of rest or inactivity, after meals, and in cold weather. Both chronic angina and unstable angina exhibit a circadian rhythm characterized by a lower angina threshold shortly after arising. Therefore morning activities such as showering, shaving, and dressing should be done at a slower pace and, if necessary, with the use of prophylactic nitroglycerin. The stress of sexual intercourse is approximately equal to that of climbing one flight of stairs at a normal pace or any activity that induces a heart rate of approximately 120 beats/min. An important dimension to effective angina control relates to the benefits of prophylactic use of short-acting nitrates (either sublingual nitroglycerin or nitrolingual pump spray). If there is a clear pattern of effort angina, prophylactic use of short-acting nitrates several minutes before engaging in the offending activity may provide sufficient vasodilation to prevent an anginal episode. In addition, with proper precautions (i.e., commencing more than 2 hours

postprandially and taking an additional dose of a short-acting beta-blocking agent 1 hour before and nitroglycerin 15 minutes before), most patients with stable angina are able to continue satisfactory sexual activity. Although it is desirable to minimize the number of bouts of angina, an occasional episode is not to be feared. Indeed, unless patients occasionally reach their angina threshold, they may not appreciate the extent of their exercise capacity. Patients with SIHD may use sildenafil, but not in conjunction with nitrates.¹⁰⁸

Pharmacologic Management of Angina

Beta Adrenoceptor–Blocking Agents

Beta-blocking agents constitute a cornerstone of therapy for angina.¹⁰⁹ In addition to their anti-ischemic properties, beta-blocking agents are effective antihypertensives (see Chapter 44) and antiarrhythmics (see Chapter 35). They have also been shown to reduce mortality and reinfarction in patients after MI (see Chapter 52) and to reduce mortality in patients with heart failure (see Chapter 25). This combination of actions makes them extremely useful in the management of SIHD. A number of studies have shown that beta blockers, in doses that are generally well tolerated, reduce the frequency of anginal episodes and raise the anginal threshold, both when given alone and when added to other antianginal agents.

The beneficial actions of these drugs depend on their ability to cause competitive inhibition of the effects of neuronally released and circulating catecholamines on beta adrenoceptors (Tables 54-4 and 54-5). Beta blockade reduces myocardial O₂ requirements, primarily by slowing the heart rate; the slower heart rate in turn increases the fraction of the cardiac cycle occupied by diastole, with a corresponding increase in the time available for coronary perfusion (Fig. 54-9; see also Table 54-4). In addition, these drugs reduce exercise-induced increases in blood pressure and limit exercise-induced increases in contractility. Thus beta-blocking agents reduce myocardial O₂ demand primarily during activity or excitement, when surges of increased sympathetic activity occur. In the presence of impaired myocardial perfusion, the effects of beta blockers on myocardial O₂ demand may critically and favorably alter the imbalance between supply and demand and thereby result in the elimination of ischemia.

Beta-blocking agents may reduce blood flow to most organs by means of the combination of unopposed alpha-adrenergic

TABLE 54-4 Effects of Antianginal Agents on Indices of Myocardial Oxygen Supply and Demand

Index	Nitrates	Beta Adrenoceptor–Blocking Agents						
		ISA		CARDIOSELECTIVE		Calcium Antagonists

BETA BLOCKADE EFFECTS ON ISCHEMIC HEART

FIGURE 54-9 Effects of beta blockade on an ischemic heart. Beta blockade has a beneficial effect on ischemic myocardium unless (1) the preload rises substantially, as in left-sided heart failure, or (2) vasospastic angina is present, in which case spasm may be promoted in some patients. Note the suggestion that beta blockade diminishes exercise-induced vasoconstriction. (Modified from Opie LH: *Drugs for the Heart*. 4th ed. Philadelphia, WB Saunders, 1995, p 6.)

vasoconstriction and beta₂ receptor blockade (Table 54-5). Complications are relatively minor, but in patients with peripheral vascular disease, the reduction in blood flow to skeletal muscles with the use of nonselective beta-blocking agents may decrease maximal exercise capacity. In patients with preexisting LV dysfunction, beta blockade may increase LV volume and thereby enhance O₂ demand.

Characteristics of Different Beta-Blocking Agents

Selectivity. Two major subtypes of beta receptors, designated beta₁ and beta₂, are present in different proportions in different tissues. Beta₁ receptors predominate in the heart, and stimulation of these receptors leads to an increase in heart rate, atrioventricular (AV) conduction, and contractility; release of renin from juxtaglomerular cells in the kidneys; and lipolysis in adipocytes. Beta₂ stimulation causes bronchodilation, vasodilation, and glycogenolysis. Nonselective beta-blocking drugs (e.g., propranolol, nadolol, penbutolol, pindolol, sotalol, timolol, carteolol) block both beta₁ and beta₂ receptors, whereas cardioselective beta-blocking agents (e.g., acebutolol, atenolol, betaxolol, bisoprolol, esmolol, metoprolol, nebivolol) block beta₁ receptors while having less effect on beta₂ receptors. Thus cardioselective beta blockers reduce myocardial O₂ requirements while tending not to block bronchodilation, vasodilation, or glycogenolysis. However, as the doses of these drugs are increased, this cardioselectivity diminishes. Because cardioselectivity is only relative, the use of cardioselective beta blockers in doses sufficient to control angina may still cause bronchoconstriction in some susceptible patients. Nevertheless, beta blockers are relatively well tolerated by most patients with obstructive pulmonary disease.

Some beta-blocking agents also cause vasodilation. Such drugs include labetalol (an alpha-adrenergic-blocking agent and beta₂-agonist; see Chapter 44), carvedilol (with alpha- and beta₁-blocking activity), bucindolol (a nonselective beta blocker that causes direct [non-alpha-adrenergic-mediated] vasodilation), and nebivolol (a cardioselective beta blocker with a direct stimulatory effect on endothelial nitric oxide synthase [eNOS]).¹¹⁰

Antiarrhythmic Actions (see Chapter 35). Beta-blocking agents have antiarrhythmic properties as a direct effect of their ability to block sympathoadrenal myocardial stimulation, which in certain situations may be arrhythmogenic.

Intrinsic Sympathomimetic Activity. Beta-blocking agents with intrinsic sympathomimetic activity (ISA), such as acebutolol, bucindolol, carteolol, celiprolol, penbutolol, and pindolol, are partial beta-agonists that also produce blockade by shielding beta receptors from more potent beta-agonists. Pindolol and acebutolol produce low-grade beta stimulation when sympathetic activity is low (at rest), whereas these partial agonists behave more like conventional beta blockers when sympathetic activity is high. Agents with ISA may not be as effective as those without this property in reducing the heart rate or the frequency, duration, and magnitude of ambulatory ST-segment changes or in increasing the duration of exercise in patients with severe angina.

Potency. Potency can be measured by the ability of beta blockers to inhibit the tachycardia produced by isoproterenol. All drugs are considered in reference to propranolol, which is given a value of 1.0 (Table 54-6). Timolol and pindolol are the most potent agents, and acebutolol and labetalol are the least potent.

Lipid Solubility. The hydrophilicity or lipid solubility of beta-blocking agents is a major determinant of their absorption and metabolism (Table 54-6). The lipid-soluble (lipophilic) beta blockers propranolol, metoprolol, and pindolol are readily absorbed from the gastrointestinal tract and metabolized predominantly by the liver. Water-soluble beta blockers, such as atenolol, are usually eliminated unchanged by the kidneys. Lipid-soluble agents are often preferable in patients with significant renal dysfunction, for whom clearance of water-soluble agents is reduced. Greater lipid solubility is associated with greater penetration into the central nervous system and may contribute to the side effects (e.g., lethargy, depression, hallucinations) that are not clearly related to beta-blocking activity.

Alpha Adrenoceptor-Blocking Activity. The alpha-blocking potency of labetalol (≈10% that of phentolamine) is approximately 20% of its beta-blocking potency (Table 54-6). Labetalol's combined alpha- and beta-blocking effects make it a particularly useful antihypertensive agent (see Chapter 44), and it is especially so in patients with hypertension and angina. The major side effects of labetalol are postural hypotension and retrograde ejaculation. Carvedilol also possesses alpha-adrenergic-blocking activity with an alpha₁-to-beta₁-blocking ratio of approximately 1:10.

Genetic Polymorphisms. The metabolism of metoprolol, carvedilol, and propranolol may be influenced by genetic polymorphisms or other medications that influence hepatic metabolism. Oxidative metabolism of metoprolol occurs primarily through the cytochrome P-450 enzyme CYP2D6 and exhibits the debrisoquin type of genetic polymorphism; poor hydroxylators or metabolizers (≤10% of white individuals) have significant prolongation of the elimination half-life of the drug in comparison to extensive hydroxylators or metabolizers.

TABLE 54-6 Pharmacokinetics and Pharmacology of Some Beta Adrenoceptor–Blocking Agents

*Determined by the distribution ratio between octanol and water.

[†]The half-life of the active metabolite diacetolol is 12 to 15 hours.

[‡]Acetolol is eliminated mainly by the liver, but its major metabolite diacetolol is excreted by the kidney.

[§]Rapid metabolism by esterases in the cytosol of red blood cells.

[¶]Beta₁ selectivity is maintained at lower doses, but beta₂ receptors are inhibited at higher doses.

FDA = U.S. Food and Drug Administration; HM = hepatic metabolism; ND = no data; RE = renal excretion.

Thus angina might be controlled by a single daily dose of metoprolol in poor metabolizers, whereas extensive metabolizers require the same dose two or three times daily. If a patient exhibits an exaggerated clinical response (e.g., extreme bradycardia) after the administration of metoprolol, propranolol, or other lipid-soluble beta blockers, it may be the result of prolongation of the elimination half-life because of slow oxidative metabolism. Metabolism of metoprolol may also be altered by drugs that interact with CYP2D6. Preliminary evidence has raised the possibility of differences in survival in patients with unstable IHD and provoked ischemia in those with SIHD treated with beta-blocking agents based on polymorphisms of the beta₂-adrenergic receptor (*ADRB1* and *ADRB2*).^{94,111}

Effects on Serum Lipid Levels. Therapy with beta blockers (those lacking ISA) usually causes no significant changes in total or LDL cholesterol levels but increases triglyceride and reduces HDL cholesterol levels. The most commonly studied drug has been propranolol, which can increase plasma triglyceride concentrations by 20% to 50% and reduce HDL cholesterol levels by 10% to 20%. Increasing beta₁ selectivity is associated with lesser effects on lipid levels. Adverse effects on the lipid profile may be more frequent with nonselective than with beta₁-selective–blocking agents.

Adverse Effects and Contraindications

Most of the adverse effects of beta-blocking agents occur as a consequence of the known properties of these drugs and include cardiac effects (e.g., severe sinus bradycardia, sinus arrest, AV block, reduced LV contractility), bronchoconstriction, fatigue, mental depression, nightmares, gastrointestinal upset, sexual dysfunction, intensification of insulin-induced hypoglycemia, and cutaneous reactions (**Table 54-7**; see also **Table 54-5**). Lethargy, weakness, and fatigue may be caused by reduced cardiac output or may arise from a direct effect on the central nervous system. In patients who already have impaired LV function, heart failure may be intensified (**see Chapter 25**). Pindolol, because of its ISA activity, may be preferable in patients with sinus node dysfunction. Carvedilol has been shown to exhibit modest insulin-sensitizing properties and can relieve some manifestations of metabolic syndrome but has been shown not to have differential effects on endothelial function when compared with metoprolol.^{112,113} Blockade of beta₂ receptors also inhibits the vasodilating effects of catecholamines in peripheral blood vessels and leaves the constrictor (alpha-adrenergic) receptors unopposed,

thereby enhancing vasoconstriction. Noncardioselective beta blockers may precipitate episodes of Raynaud phenomenon in patients with this condition and may cause uncomfortable coldness in the distal extremities. Reduced flow to the limbs may occur in patients with peripheral vascular disease.

Abrupt withdrawal of beta blockers after prolonged administration can result in increased total ischemic activity in patients with chronic stable angina. Chronic beta blocker therapy can be safely discontinued by slowly withdrawing the drug in a stepwise manner over the course of 2 to 3 weeks. If abrupt withdrawal of beta blockers

is required, patients should be instructed to reduce exertion and manage angina episodes with sublingual nitroglycerin and/or substitute a calcium antagonist.

Calcium Antagonists
